anastomosing vessels: "The principal communications by which the circulation was carried on, were:—Firstly, the internal mammary, anastomosing with the intercostal arteries, with the phrenic of the abdominal aorta by means of the musculo-phrenic and comissura phrenici, and largely with the deep epigastric. Secondly, the superior intercostal, anastomosing anteriorly by means of a large branch with the first aortic intercostal, and posteriorly with the posterior branch of the same artery. Thirdly, the inferior thyroid, by means of a branch about the size of an ordinary radial, formed a communication with the first aortic intercostal. Fourthly, the transversalis colli, by means of very large communications with the posterior branches of the intercostals. Fifthly, the branches (of the subclavian and axillary) going to the side of the chest were large, and anastomosed freely with the lateral branches of the intercostals." "

**Surgical Anatomy.**—The student should now consider the effects likely to be produced by aneurism of the thoracic aorta, a disease of common occurrence. When we consider the great depth of the vessel from the surface and the number of important structures which surround it on every side, it may easily be conceived what a variety of obscure symptoms may arise from disease of this part of the arterial system, and how they may be liable to be mistaken for those of other affections. Aneurism of the thoracic aorta most usually extends backward along the left side of the spine, producing absorption of the bodies of the vertebrae, with curvature of the spine; whilst the irritation or pressure on the cord will give rise to pain, either in the chest, back, or loins, with radiating pain in the left upper intercostal spaces, from pressure on the intercostal nerves; at the same time the tumor may project backward on each side of the spine, beneath the integument, as a pulsating swelling, simulating abscess connected with diseased bone, or it may displace the oesophagus and compress the lung on one or the other side. If the tumor extend forward, it may press upon and displace the heart, giving rise to palpitation and other symptoms of disease of that organ; or it may displace, or even compress, the oesophagus, causing pain and difficulty of swallowing, as in stricture of that tube; and ultimately even open into it by ulceration, producing fatal haemorrhage. If the disease extends to the right side, it may press upon the thoracic duct; or it may burst into the pleural cavity or into the trachea or lung; and lastly, it may open into the posterior mediastinum.

**Branches of the Thoracic Aorta.**

**Pericardial.**

**Esophageal.**

**Bronchial.**

**Posterior Mediastinal.**

**Intercostal.**

The **pericardial** are a few small vessels, irregular in their origin, distributed to the pericardium.

The **bronchial arteries** are the nutrient vessels of the lungs, and vary in number, size, and origin. That of the right side arises from the first aortic intercostal, or by a common trunk with the left bronchial from the front of the thoracic aorta. Those of the left side, usually two in number, arise from the thoracic aorta, one a little lower than the other. Each vessel is directed to the back part of the corresponding bronchus along which it runs, dividing and subdividing upon the bronchial tube, supplying them, the cellular tissue of the lungs, the bronchial glands, and the oesophagus.

The **oesophageal arteries**, usually four or five in number, arise from the front of the aorta, and pass obliquely downward to the oesophagus, forming a chain of anastomoses along that tube, anastomosing with the oesophageal branches of the inferior thyroid arteries above, and with ascending branches from the phrenic and gastric arteries below.

The **posterior mediastinal arteries** are numerous small vessels which supply the glands and loose areolar tissue in the mediastinum.

The **intercostal arteries** arise from the back part of the aorta. They are usually eleven in number on each side, the superior intercostal space being supplied by the superior intercostal, a branch of the subelavian, and the second intercostal space being supplied by a branch from the superior intercostal joining with the first aortic intercostal. The lowest of these branches, the **subcostal artery**, underlies the last rib. The right intercostals are longer than the left, on account of the position of the aorta on the left side of the spine; they pass outward, across the bodies of the vertebrae, to the intercostal spaces, being covered by the pleura, the
oesophagus, thoracic duct, sympathetic nerve, and the vena azygos major; the left passing beneath the superior intercostal vein, the vena azygos minor, and sympathetic. In the intercostal spaces each artery divides into two branches—an anterior, or proper intercostal branch; and a posterior, or dorsal branch.¹

The anterior branch passes outward, at first lying upon the External inter-

costal muscle, covered in front by the pleura and a thin fascia. It then passes between the two layers of Intercostal muscles, and, having ascended obliquely to the lower border of the rib above, divides near the angle of that bone, into two branches: of these the larger runs in the groove on the lower border of the rib above; the smaller branch along the upper border of the rib below; passing

¹ Mr. W. J. Walsham describes a small twig as being given off from each intercostal close to its origin. He states that they can be traced running between the neck of the rib and the transverse process of the corresponding vertebra; they anastomose with similar twigs given off from the intercostal artery next below. In the first and second spaces similar anastomosing twigs are given off from the superior intercostal (Journal of Anatomy and Physiology, vol. xvi. part iii. p. 443).
forward, they supply the Intercostal muscle, and anastomose with the anterior intercostal branches of the internal mammary, and with the thoracic branches of the axillary artery. The first aortic intercostal anastomoses with the superior intercostal, and the last three pass between the abdominal muscles, inosculating with the epigastric in front and with the phrenic and lumbar arteries. Each intercostal artery is accompanied by a vein and nerve, the former being above, and the latter below, except in the upper intercostal spaces, where the nerve is at first above the artery. The arteries are protected from pressure during the action of the Intercostal muscles by fibrous arches thrown across, and attached by each extremity to the bone. The lower intercostal arteries are continued anteriorly from the intercostal spaces into the abdominal wall, except the last, the subcostal, which lies throughout its whole course in the abdominal wall, since it is placed below the last rib. They pass behind the costal cartilages between the Internal oblique and Transversalis muscle to the sheath of the Rectus, where they anastomose with the internal mammary and the deep epigastric arteries. Behind, the subcostal artery anastomoses with the first lumbar artery.

The posterior or dorsal branch of each intercostal artery passes backward to the inner side of the anterior costo-transverse ligament, and divides into a muscular branch which is distributed to the muscles and integument of the back, and a spinal branch which enters the spinal canal through the intervertebral foramina to be distributed to the spinal cord and its membranes, and to the bodies of the vertebrae in the same manner as the lateral spinal branches from the vertebral.

**THE ABDOMINAL AORTA** (Fig. 367).

The Abdominal Aorta commences at the aortic opening of the Diaphragm, in front of the body of the last dorsal vertebra, and, descending a little to the left side of the vertebral column, terminates on the body of the fourth lumbar vertebra, commonly a little to the left of the middle line, where it divides into the two common iliac arteries. It diminishes rapidly in size, in consequence of the many large branches which it gives off. As it lies upon the bodies of the vertebrae the curve which it describes is convex forward, the greatest convexity corresponding to the third lumbar vertebra, which is a little above and to the left side of the umbilicus.

**Relations.**—It is covered, in front, by the lesser omentum and stomach, behind which are the branches of the celiac axis and the solar plexus; below these, by the splenic vein, the pancreas, the left renal vein, the transverse portion of the duodenum, the mesentery, and aortic plexus. **Behind,** it is separated from the lumbar vertebrae by the left lumbar veins, the receptaculum chyli, and thoracic duct. **On the right side** it is in relation with the inferior vena cava (the right crus of the Diaphragm being interposed above), the vena azygos major, thoracic duct, and right semilunar ganglion; on the left side, with the sympathetic nerve and left semilunar ganglion.

**Plan of the Relations of the Abdominal Aorta.**

- Transverse duodenum.
- Mesentery.
- Aortic plexus.

1 Sir Joseph Lister, having accurately examined 30 bodies in order to ascertain the exact point of termination of this vessel, found it "either absolutely, or almost absolutely, mesial in 15, while in 13 it deviated more or less to the left, and in 2 was slightly to the right" (System of Surgery, edited by T. Holmes, 2d ed. vol. v. p. 652).

Surface Marking.—In order to map out the abdominal aorta on the surface of the abdomen, a line must be drawn from the middle line of the body, on a level with the distal extremity of the seventh costal cartilage, downward and slightly to the left, so that it just skirts the umbilicus, to a zone drawn round the body opposite the highest point of the crest of the ilium. This point is generally half an inch below and to the left of the umbilicus, but as the position of this structure varies with the obesity of the individual, it is not a reliable landmark as to the situation of the bifurcation of the aorta.

Surgical Anatomy.—Aneurisms of the abdominal aorta near the coeliac axis communicate in nearly equal proportion with the anterior and posterior parts of the artery.
When an aneurismal sac is connected with the back part of the abdominal aorta, it usually produces absorption of the bodies of the vertebrae, and forms a pulsating tumor that presents itself in the left hypochondriac or epigastric regions, and is accompanied by symptoms of disturbance in the alimentary canal. Pain is invariably present, and is usually of two kinds—a fixed and constant pain in the back, caused by the tumor pressing on or displacing the branches of the solar plexus and splanchnic nerves; and a sharp lancinating pain, radiating along those branches of the lumbar nerves which are pressed on by the tumor; hence in the loins, the testes, the hypogastrum, and in the lower limb (usually of the left side). This form of aneurism usually bursts into the peritoneal cavity or behind the peritoneum in the left hypochondriac region; or it may form a large aneurismal sac, extending down as low as Poupard's ligament; haemorrhage in these cases being generally very extensive, but slowly produced, and not rapidly fatal.
When an aneurismal sac is connected with the front of the aorta near the coeliac axis, it forms a pulsating tumor in the left hypochondriac or epigastric regions, usually attended with symptoms of disturbance of the alimentary canal, as sickness, dyspepsia, or constipation, and accompanied by pain, which is constant, but nearly always fixed in the loins, epigastrum, or some part of the abdomen; the radiating pain being rare, as the lumbar nerves are seldom implicated. This form of aneurism may burst into the peritoneal cavity or behind the peritoneum, between the layers of the mesentery, or, more rarely, into the duodenum; it rarely extends backward so as to affect the spine.
The abdominal aorta has been tied several times, and although none of the patients permanently recovered, still, as one of them lived as long as ten days, the possibility of the re-establishment of the circulation may be considered to be proved. In the lower animals this artery has been often successfully tied. The vessel may be reached in several ways. In the original operation, performed by Sir A. Cooper, an incision was made in the linea alba, the peritoneum opened in front, the finger carried down amongst the intestines toward the spine, the peritoneum again opened behind by scratching through the mesentery, and the vessel thus reached. Or either of the operations described below for securing the common iliac artery may, by extending the dissection a sufficient distance upward, be made use of to expose the aorta. The chief difficulty in the dead subject consists in isolating the artery in consequence of its great depth; but in the living subject the embarrassment resulting from the proximity of the aneurismal tumor, and the great probability of disease in the vessel itself, add to the dangers and difficulties of this formidable operation so greatly that it is very doubtful whether it ought ever to be performed.
The collateral circulation would be carried on by the anastomosis between the internal mammary and the deep epigastric; by the free communication between the superior and inferior mesenteries if the ligature were placed above the latter vessel; or by the anastomosis between the inferior mesenteric and the internal pudic when (as is more common) the point of ligature is below the origin of the inferior mesenteric; and possibly by the anastomoses of the lumbar arteries with the branches of the internal iliac.
The circulation through the abdominal aorta may be commanded, in thin persons, by firm pressure with the fingers. A tourniquet has been invented for this purpose which is sometimes used in amputation at the hip-joint and some other operations.

**Visceral Branches of the Abdominal Aorta.**

**The Celiac Axis** (Fig. 368).

To expose this artery raise the liver, draw down the stomach, and then tear through the layers of the lesser omentum.

The *Celiac Axis* is a short thick trunk, about half an inch in length, which arises from the aorta opposite the margin of the Diaphragm, and, passing nearly horizontally forward (in the erect posture), divides into three large branches, the *gastric*, *hepatic*, and *splenic*, occasionally giving off one of the phrenic arteries.

**Relations.**—It is covered by the lesser omentum. On the *right side* it is in relation with the right semilunar ganglion, and the lobus Spigelii; on the *left side*, with the left semilunar ganglion and cardiac end of the stomach. *Below*, it rests upon the upper border of the pancreas.
The *Gastric Artery* (*Coronaria ventriculi*), the smallest of the three branches of the coeliac axis, passes upward and to the left side, to the cardiac orifice of the stomach, distributing branches to the oesophagus which anastomose with the aortic oesophageal arteries; others supply the cardiac end of the stomach, inosculating with branches of the splenic artery; it then passes from left to right, along the lesser curvature of the stomach to the pylorus, lying in its course between the layers of the lesser omentum, and giving branches to both surfaces of the organ: at its termination it anastomoses with the pyloric branch of the hepatic.

The *Hepatic Artery* in the adult is intermediate in size between the gastric and splenic; in the foetus it is the largest of the three branches of the coeliac axis. It is first directed forward and to the right, to the upper margin of the pyloric end of the stomach, crossing under the foramen of Winslow. It then passes upward between the layers of the lesser omentum, near the anterior margin of the foramen of Winslow, to the transverse fissure of the liver, where it divides into two branches, right and left, which supply the corresponding lobes of that organ, accompanying the ramifications of the vena portae and hepatic duct. The hepatic artery, in its course along the right border of the lesser omentum, is in relation with the ductus communis choledochus and portal veins, the duct lying to the right of the artery and the vena portae behind.

Its branches are—the

Pyloric.

Gastro-duodenalis  
\[\text{Gastro-epiploica Dextra.}\]

\[\text{Pancreatico-duodenalis Superior.}\]

Cystic.

The pyloric branch arises from the hepatic, above the pylorus, descends to the pyloric end of the stomach, and passes from right to left along its lesser curvature, supplying it with branches and inosculating with the gastric artery.

The gastro-duodenalis (Fig. 369) is a short but large branch which descends, near the pylorus, behind the first portion of the duodenum, at the lower border of which it divides into two branches, the *gastro-epiploica dextra* and the *pancreatico-duodenalis superior*. Previous to its division it gives off two or three small inferior pyloric branches to the pyloric end of the stomach and pancreas.

The *gastro-epiploica dextra* runs from right to left along the greater curvature of the stomach, between the layers of the great omentum, anastomosing about the middle of the lower border of the stomach with the gastro-epiploica sinistra from the splenic artery. This vessel gives off numerous branches, some of which ascend to supply both surfaces of the stomach, whilst others descend to supply the great omentum.

The pancreatico-duodenalis superior descends between the contiguous margins of the duodenum and pancreas. It supplies both these organs, and anastomoses with the inferior pancreatico-duodenal branch of the superior mesenteric artery and with the pancreatic branches of the splenic.

The *cystic artery* (Fig. 368), usually a branch of the right hepatic, passes upward and forward along the neck of the gall-bladder, and divides into two branches, one of which ramifies on its free surface, the other between it and the substance of the liver.

The *Splenic Artery*, in the adult, is the largest of the three branches of the coeliac axis, and is remarkable for the extreme tortuosity of its course. It passes horizontally to the left side along the upper border of the pancreas, accompanied by the splenic vein, which lies below it, and on arriving near the spleen divides into branches, some of which enter the hilum of that organ to be distributed to its structure, whilst others are distributed to the great end of the stomach. Its branches are—the

Pancreatice Parve.  
Pancreatice Magna.  

Gastric (Vasa Brevia).  
Gastro-epiploica Sinistra.
The pancreatic are numerous small branches derived from the splenic as it runs behind the upper border of the pancreas, supplying its middle and left parts. One of these, larger than the rest, is given off from the splenic near the left extremity of the pancreas; it runs from left to right near the posterior surface of the gland, following the course of the pancreatic duct, and is called the *pancreatica magna*. These vessels anastomose with the pancreatic branches of the pancreatico-

duodenal arteries, derived from the hepatic on the one hand and superior mesenteric on the other.

The *gastric* (*vasa brevia*) consists of from five to seven small branches, which arise either from the termination of the splenic artery or from its terminal branches, and, passing from left to right, between the layers of the gastro-splenic omentum, are distributed to the great curvature of the stomach, anastomosing with branches of the gastric and gastro-epiploica sinistra arteries.

The *gastro-epiploica sinistra*, the largest branch of the splenic, runs from left to right along the great curvature of the stomach, between the layers of the great omentum, and anastomoses with the gastro-epiploica dextra. In its course it distributes several branches to the stomach, which ascend upon both surfaces; others descend to supply the omentum.

**The Superior Mesenteric Artery** (Fig. 370).

In order to expose this vessel raise the great omentum and transverse colon, draw down the small intestines, and cut through the peritoneum where the transverse meso-colon and mesen-
The Superior Mesenteric Artery joins the artery will then be exposed just as it issues from beneath the lower border of the pancreas.

The Superior Mesenteric Artery supplies the whole length of the small intestine, except the first part of the duodenum; it also supplies the cæcum, ascending and transverse colon; it is a vessel of large size, arising from the fore part of the aorta about a quarter of an inch below the cœliac axis; being covered at its origin by the splenic vein and pancreas. It passes forward, between the pancreas and transverse portion of the duodenum, crosses in front of this portion of the in-testine, and descends between the layers of the mesentery to the right iliac fossa, where it terminates, considerably diminished in size. In its course it forms an arch, the convexity of which is directed forward and downward to the left side, the concavity backward and upward to the right. It is accompanied by the superior mesenteric vein, and is surrounded by a superior mesenteric plexus of nerves. Its branches are—the

Inferior Pancreatique-duodenal. Ileo-colic.
Vasa Intestini Tenuis. Colica Dextra.

Colica Media.

The Inferior pancreatique-duodenal is given off from the superior mesenteric behind the pancreas, and is distributed to the head of the pancreas with the
transverse and descending portions of the duodenum, anastomosing with the superior pancreatico-duodenal artery.

The *vasa intestini tenus* arise from the convex side of the superior mesenteric artery. They are usually from twelve to fifteen in number, and are distributed to the jejunum and ileum. They run parallel with one another between the layers of the mesentery, each vessel dividing into two branches, which unite with a similar branch on each side, forming a series of arches the convexities of which are directed toward the intestine. From this first set of arches branches arise, which again unite with similar branches from either side, and thus a second series of arches is formed; and from these latter, a third, and a fourth, or even fifth, series of arches is constituted, diminishing in size the nearer they approach the intestine. From the terminal arches numerous small straight vessels arise which encircle the intestine, upon which they are distributed, ramifying thickly between its coats.

The *ileo-colic artery* is the lowest branch given off from the concavity of the superior mesenteric artery. It descends between the layers of the mesentery to the right iliac fossa, where it divides into two branches. Of these, the inferior one inosculates with the lowest branches of the vasa intestini tenus, from the convexity of which branches proceed to supply the termination of the ileum, the caecum and appendix ceeci, and the ileo-cecal valve. The superior division inosculates with the colica dextra and supplies the commencement of the colon.

The *colica dextra* arises from about the middle of the concavity of the superior mesenteric artery, and, passing behind the peritoneum to the middle of the ascending colon, divides into two branches—a descending branch, which inosculates with the ileo-colic; and the ascending branch, which anastomoses with the colica media. These branches form arches, from the convexity of which vessels are distributed to the ascending colon. The branches of this vessel are covered with peritoneum only on their anterior aspect.

The *colica media* arises from the upper part of the concavity of the superior mesenteric artery, and, passing forward between the layers of the transverse meso-colon, divides into two branches, the one on the right side inosculating with the colica dextra; that on the left side, with the colica sinistra, a branch of the inferior mesenteric. From the arches formed by their inosculation branches are distributed to the transverse colon. The branches of this vessel lie between two layers of peritoneum.

**The Inferior Mesenteric Artery** (Fig. 371).

In order to expose this vessel draw the small intestines and mesentery over to the right side of the abdomen, raise the transverse colon toward the thorax, and divide the peritoneum covering the left side of the aorta.

The *Inferior Mesenteric Artery* supplies the descending and sigmoid flexure of the colon and the greater part of the rectum. It is smaller than the superior mesenteric, and arises from the left side of the aorta, between one and two inches above its division into the common iliacs. It passes downward to the left iliac fossa, and then descends, between the layers of the meso-rectum, into the pelvis, under the name of the *superior hæmorrhoidal artery*. It lies at first in close relation with the left side of the aorta, and then passes as the superior hæmorrhoidal in front of the left common iliac artery. Its branches are—the

*Colica Sinistra.*

*Superior Hæmorrhoidal.*

*Sigmoid.*

The *colica sinistra* passes behind the peritoneum, in front of the left kidney, to reach the descending colon, and divides into two branches—an ascending branch, which inosculates with the colica media; and a descending branch, which anastomoses with the sigmoid artery. From the arches formed by these inosculation branches are distributed to the descending colon.

The *sigmoid artery* runs obliquely downward across the Psoas muscle to the
sigmoid flexure of the colon, and divides into branches which supply that part of
the intestine, anastomosing above with the colica sinistra, and below with the
superior haemorrhoidal artery. This vessel is sometimes replaced by three or four
small branches.

The superior haemorrhoidal artery, the continuation of the inferior mesenteric,
descends into the pelvis between the layers of the meso-rectum, crossing, in its
course, the ureter and left common iliac vessels. It divides into two branches,
which descend one on each side of the rectum, and about five inches from the anus
break up into several small branches, which are distributed between the mucous
and muscular coats of that tube, nearly as far as its lower end, anastomosing
with each other, with the middle haemorrhoidal arteries, branches of the internal
iliac, and with the inferior haemorrhoidal branches of the internal pudic.

The Suprarenal Arteries.

The suprarenal arteries (Fig. 367) (middle suprarenal) are two small vessels
which arise, one on each side of the aorta, opposite the superior mesenteric artery.
They pass obliquely upward and outward, over the crura of the Diaphragm, to
the under surface of the suprarenal capsules, to which they are distributed, anasto-
mosing with capsular branches from the phrenic and renal arteries. In the adult
these arteries are of small size; in the fetus they are as large as the renal arteries.
The Renal Arteries.

The renal arteries are two large trunks which arise from the sides of the aorta immediately below the superior mesenteric artery. Each is directed outward across the crus of the Diaphragm, so as to form nearly a right angle with the aorta. The right is longer than the left, on account of the position of the aorta; it passes behind the inferior vena cava. The left is somewhat higher than the right. Previously to entering the kidney each artery divides into four or five branches which are distributed to its substance. At the hilum these branches lie between the renal vein and ureter, the vein being usually in front, the ureter behind. Each vessel gives off some small branches (inferior suprarenal) to the suprarenal capsule, the ureter, and the surrounding cellular tissue and muscles. Frequently there is a second renal artery, which is given off from the abdominal aorta at a lower level and supplies the lower portion of the kidney. It is termed the inferior renal artery.

The Spermatic Arteries.

The spermatic arteries are distributed to the testes in the male and to the ovaria in the female. They are two slender vessels, of considerable length, which arise from the front of the aorta a little below the renal arteries. Each artery passes obliquely outward and downward behind the peritoneum, resting on the Psoas muscle, the right spermatic lying in front of the inferior vena cava, the left behind the sigmoid flexure of the colon. It then crosses obliquely over the ureter and the lower part of the external iliac artery to reach the internal abdominal ring, through which it passes, and accompanies the other constituents of the spermatic cord along the inguinal canal to the scrotum, where it becomes tortuous, and divides into several branches, two or three of which accompany the vas deferens and supply the epididymis, anastomosing with the artery of the vas deferens; others pierce the back part of the tunica albuginea, and supply the substance of the testis.

The Ovarian Arteries.

The ovarian arteries are shorter than the spermatic, and do not pass out of the abdominal cavity. The origin and course of the first part of the artery are the same as the spermatic in the male, but on arriving at the margin of the pelvis the ovarian artery passes inward, between the two laminae of the broad ligament of the uterus, to be distributed to the ovary. One or two small branches supply the Fallopian tube; another passes on to the side of the uterus and anastomoses with the uterine arteries. Other offsets are continued along the round ligament, through the inguinal canal, to the integument of the labium and groin.

At an early period of fetal life, when the testes or ovaries lie by the side of the spine below the kidneys, the spermatic or ovarian arteries are short; but as these organs descend from the abdomen into the scrotum the arteries become gradually lengthened.

Parietal Branches of the Abdominal Aorta.

The Phrenic Arteries.

The phrenic arteries are two small vessels which present much variety in their origin. They may arise separately from the front of the aorta, immediately above the celiac axis, or by a common trunk, which may spring either from the aorta or from the celiac axis. Sometimes one is derived from the aorta, and the other from one of the renal arteries. In only one out of thirty-six cases examined did these arteries arise as two separate vessels from the aorta. They diverge from one another across the crura of the Diaphragm, and then pass obliquely upward and outward upon its under surface. The left phrenic passes behind the oesophagus and runs forward on the left side of the oesophageal opening. The right phrenic passes behind the inferior vena cava, and ascends along the right side of the aperture for transmitting that vein. Near the back part of the central tendon each vessel divides into two branches. The internal branch runs forward to the front of the thorax, supplying the Diaphragm and anastomosing with its fellow of
the opposite side, and with the musculo-phrenic and comes nervi phrenici, branches of the internal mammary. The external branch passes toward the side of the thorax and inosculates with the intercostal arteries. The internal branch of the right phrenic gives off a few vessels to the inferior vena cava, and the left one some branches to the oesophagus. Each vessel also sends capsular branches (superior suprarenal) to the suprarenal capsulse of its own side. The spleen on the left side and the liver on the right also receive a few branches from these vessels.

The Lumbar Arteries.

The lumbar arteries are analogous to the intercostal. They are usually four in number on each side, and arise from the back part of the aorta, nearly at right angles with that vessel. They pass outward and backward, around the sides of the body of the lumbar vertebra, behind the sympathetic nerve and the Psoas magnus muscle, those on the right side being covered by the inferior vena cava, and the two upper ones on each side by the crura of the Diaphragm. In the interval between the transverse processes of the vertebrae each artery divides into a dorsal and an abdominal branch.

The dorsal branch gives off, immediately after its origin, a spinal branch, which enters the spinal canal; it then continues its course backward between the transverse processes, and is distributed to the muscles and integument of the back, anastomosing with the similar branches of the adjacent lumbar arteries and with the posterior branches of the intercostal arteries.

The spinal branch enters the spinal canal through the intervertebral foramen, to be distributed to the spinal cord and its membranes and to the bodies of the vertebrae in the same manner as the lateral spinal branches from the vertebral (see page 582).

The abdominal branches pass outward, having a variable relation to the Quadratus lumborum muscle. Most frequently the first branch passes in front of the muscle and the others behind it; sometimes the order is reversed and the lowest branch passes in front of the muscle. At the outer border of the Quadratus they are continued between the abdominal muscles, anastomose with branches of the epigastric and internal mammary in front, the intercostals above, and those of the ilio-lumbar and circumflex iliac below.

The Sacra Media.

The Middle Sacral Artery is a small vessel about the size of a crow-quill, which arises from the back part of the aorta just at its bifurcation. It descends upon the last lumbar vertebra, and along the middle line of the front of the sacrum, to the upper part of the coccyx, where it anastomoses with the lateral sacral arteries, and terminates in a minute branch, which runs down to the situation of the body presently to be described as "Luschka's gland." From it branches arise which run through the meso-rectum to supply the posterior surface of the rectum. Other branches are given off on each side, which anastomose with the lateral sacral arteries, and send off small offsets which enter the anterior sacral foramina.

The artery is the representative of the caudal prolongation of the aorta of animals, and its lateral branches correspond to the intercostal and lumbar arteries in the dorsal and lumbar regions.

Coccygeal Gland, or Luschka's Gland.—Lying near the tip of the coccyx in a small tendinous interval formed by the union of the Levator ani muscles of each side, and just above the coccygeal attachment of the Sphincter ani, is a small conglobate body about as large as a lentil or a pea, first described by Luschka, and named by him the coccygeal gland. Its most obvious connections are with the arteries of the part.

Structure.—It consists of a congeries of small arteries with little aeurismal dilatations derived from the middle sacral and freely communicating with each

other. These vessels are enclosed in one or more layers of polyhedral granular cells, and the whole structure is invested in a capsule of connective tissue which sends in trabecule, dividing the interior into a number of spaces in which the vessels and cells are contained. Nerves pass into this little body from the sympathetic, but their mode of termination is unknown. Macalister believes the glomerulus of vessels "consists of the condensed and convoluted metamerie dorsal arteries of the caudal segments imbedded in tissue which is possibly a small persisting fragment of the neureneretric canal."

**THE COMMON ILIAC ARTERIES.**

The abdominal aorta divides into the two *common iliac arteries*. The bifurcation usually takes place on the left side of the body of the fourth lumbar vertebra. This point corresponds to the left side of the umbilicus, and is on a level with a line drawn from the highest point of one iliac crest to the other. The common iliac arteries are about two inches in length; diverging from the termination of the aorta, they pass downward and outward to the margin of the pelvis, and divide opposite the intervertebral substance, between the last lumbar vertebra and the sacrum into two branches, the *external* and *internal iliac arteries*, the former supplying the lower extremity; the latter, the viscera and parietes of the pelvis.

The *right common iliac* is somewhat larger than the left, and passes more obliquely across the body of the last lumbar vertebra. In front of it are the peritoneum, the small intestine, branches of the sympathetic nerve, and, at its point of division, the ureter. *Behind*, it is separated from the last two lumbar vertebrae by the two common iliac veins. On its *outer side*, it is in relation with the inferior vena cava and the right common iliac vein, and the Psoas magnus muscle below.

The *left common iliac* is in relation, in front, with the peritoneum, the small intestine, branches of the sympathetic nerve, and the superior haemorrhoidal artery, and is crossed at its point of bifurcation by the ureter. The left common iliac vein lies partly on the inner side and partly beneath the artery; on its outer side the artery is in relation with the Psoas magnus muscle.

**PLAN OF THE RELATIONS OF THE COMMON ILIAC ARTERIES.**

- Right common iliac vein.
- Psoas muscle.

*Inner side.*
- Left common iliac vein.

*Behind.*
- Last two lumbar vertebrae.
- Right and left common iliac veins.

Branches.—The common iliac arteries give off small branches to the peritoneum Psoas magnus, ureters, and the surrounding cellular tissue, and occasionally give origin to the ilio-lumbar or renal arteries.

Peculiarities.—The *point of origin* varies according to the bifurcation of the aorta. In three-fourths of a large number of cases the aorta bifurcated either upon the fourth lumbar vertebra or upon the intervertebral disk between it and the fifth, the bifurcation being, in one case out of nine below, and in one out of eleven above, this point. In ten out of every thirteen cases the vessel bifurcated within half an inch above or below the level of the crest of the ilium more frequently below than above.

The *point of division* is subject to great variety. In two-thirds of a large number of cases it was between the last lumbar vertebra and the upper border of the sacrum being above that.
point in one case out of eight; and below it in one case out of six. The left common iliac artery divides lower down more frequently than the right.

The relative length, also, of the two common iliac arteries varies. The right common iliac was the longer in sixty-three cases, the left in fifty-two, whilst they were both equal in fifty-three. The length of the arteries varied in five-sevenths of the cases examined from an inch and a half to three inches; in about half of the remaining cases the artery was longer and in the other half shorter, the minimum length being less than half an inch, the maximum four and a half inches. In two instances the right common iliac has been found wanting, the external and internal iliacs arising directly from the aorta.

Surface Marking.—Draw a zone round the body opposite the highest part of the crest of the ilium; in this line take a point half an inch to the left of the middle line. From this

draw two lines to points midway between the anterior superior spines of the ilium and the symphysis pubis. These two diverging lines will represent the course of the common and external iliac arteries. Draw a second zone round the body corresponding to the level of the anterior superior spines of the ilium: the portion of the diverging lines between the two zones will represent the course of the common iliac artery; the portion below the lower zone, that of the external iliac artery.

Surgical Anatomy.—The application of a ligature to the common iliac artery may be required on account of aneurism or hemorrhage implicating the external or internal iliacs. The artery may be tied by one or two incisions: 1. an anterior or iliac incision, by which the vessel is approached more directly from the front; and 2. a posterior abdominal or lumbar incision, by which the vessel is reached from behind. If the surgeon select the iliac region, a curved incision, from five to eight inches in length according to the amount of fat, is made, commencing just outside the middle of Poupart's ligament and a finger's breadth above it, and carried outward toward the anterior superior iliac spine, then upward toward the ribs, and finally curving inward
toward the umbilicus. The abdominal muscles and transversalis fascia are divided, and the psoas raised upward and inward until the psoas is reached. The artery will be found on the inner side of this muscle, and is to be cleared with a director, especial care being taken on the right side, as here the common iliac veins lie behind the artery. The aneurism needle is to be passed from within outward. But if the aneurismal tumor should extend high up in the abdomen, along the external iliac, it is better to select the posterior or lumbar, by making an incision partly in the abdomen, partly in the loin. The incision is commenced at the anterior extremity of the last rib, proceeding directly downward to the ilium; it is then curved forward along the crest of the ilium and a little above it to the anterior superior spine of that bone. The abdominal muscles have been cautiously divided in succession, the transversalis fascia must be carefully cut through, and the peritoneum, together with the ureter, separated from the artery and pushed aside; the sacro-iliac articulation must then be felt for, and upon it the vessel will be felt pulsating, and may be fully exposed in close connection with its accompanying vein. On the right side both common iliac veins, as well the inferior vena cava, are in close connection with the artery, and must be carefully avoided. On the left side the vein usually lies on the inner side and behind the artery; but it occasionally happens that the two common iliac veins are joined on the left instead of the right side, which would add much to the difficulty of an operation in such a case. The common iliac artery may be so short that danger may be apprehended from secondary haemorrhage if a ligature is applied to it. It would be preferable, in such a case, to tie both the external and internal iliacs near their origin.

Collateral Circulation.—The principal agents in carrying on the collateral circulation after the application of a ligature to the common iliac are—the anastomoses of the hemorrhoidal branches of the internal iliac with the superior hemorrhoidal from the inferior mesenteric; the anastomoses of the uterine and ovarian arteries and of the vesical arteries of opposite sides; of the lateral sacral with the middle sacral artery; of the epigastric with the internal mammary, inferior intercostal, and lumbar arteries; of the circumflex iliac with the lumbar arteries; of the ilio-lumbar with the last lumbar artery; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side, and with the deep epigastric.

Compression of the Common Iliac Arteries.—The common iliac arteries are most efficiently compressed by Davy’s lever. The instrument consists of a gum-elastic tube about two feet long, in which fits a round wooden “lever” considerably longer than the tube. A small quantity of olive oil having been injected into the rectum, the gum-elastic tube, softened in hot water, is passed into the bowel sufficiently far to permit its pressing upon the common iliac artery as it lies in the groove between the last lumbar vertebra and the psoas muscle. The wooden lever is then inserted into the tube, and the projecting end carried toward the opposite thigh and raised, when it acts as a lever of the first order, the anus being the fulcrum. In cases where the meso-rectum is abnormally short it may be impossible, without unjustifiable force, to compress the artery on the right side.

Internal Iliac Artery (Fig. 372).

The internal iliac artery supplies the walls and viscera of the pelvis, the generative organs, and inner side of the thigh. It is a short, thick vessel, smaller in the adult than the external iliac, and about an inch and a half in length. It arises at the point of bifurcation of the common iliac, and, passing downward to the upper margin of the great sacro-sciatic foramen, divides into two large trunks, an anterior and posterior; from its point of bifurcation a partially obliterated cord, the hypogastric artery, extends forward to the bladder.

Relations.—In front, with the ureter, which separates it from the peritoneum. Behind, with the internal iliac vein, the lumbo-sacral nerve, and Pyriformis muscle. By its outer side, near its origin, with the Psoas magnus muscle.

In the fetus the internal iliac artery (hypogastric) is twice as large as the external iliac, and appears to be the continuation of the common iliac. Instead of dipping into the pelvis, it passes forward to the bladder, and ascends along the sides of that viscus to its summit, to which it gives branches; it then passes upward along the back part of the anterior wall of the abdomen to the umbilicus, converging toward its fellow of the opposite side. Having passed through the umbilical opening, the two arteries twine round the umbilical vein, forming with it the umbilical cord, and ultimately ramify in the placenta. The portion of the vessel within the abdomen is called the hypogastric artery, and that external to that cavity, the umbilical artery.

At birth, when the placental circulation ceases, the upper portion of the hypogastric artery, extending from the summit of the bladder to the umbilicus, contracts, and ultimately dwindles to a solid fibrous cord; but the lower portion, extending from its origin (in what is now the internal iliac artery) for about an inch and a half to the wall of the bladder, and thence to the summit of that organ, is not totally impervious, though it becomes considerably reduced in size, and serves to convey blood to the bladder under the name of the superior vesical artery.

Peculiarities as regards Length.—In two-thirds of a large number of cases the length of the internal iliac varied between an inch and an inch and a half; in the remaining third it was more frequently longer than shorter, the maximum length being three inches, the minimum half an inch.

The lengths of the common and internal iliac arteries bear an inverse proportion to each other, the internal iliac artery being long when the common iliac is short, and vice versa.

As regards its Place of Division.—The place of division of the internal iliac varies between the upper margin of the sacrum and the upper border of the sacro-scatic foramen.

The arteries of the two sides in a series of cases often differed in length, but neither seemed constantly to exceed the other.

Surgical Anatomy.—The application of a ligature to the internal iliac artery may be required in cases of aneurism or haemorrhage affecting one of its branches. The vessel may be secured by making an incision through the abdominal parietes in the iliac region in a direction and to an extent similar to that for securing the common iliac; the transversalis fascia having been cautiously divided, and the peritoneum pushed inward from the iliac fossa toward the pelvis, the finger may feel the pulsation of the external iliac at the bottom of the wound, and by tracing this vessel upward the internal iliac is arrived at, opposite the sacro-iliaic articulation. It should be remembered that the vein lies behind and on the right side, a little external to the artery, and in close contact with it; the ureter and peritoneum, which lie in front, must also be avoided. The degree of facility in applying a ligature to this vessel will mainly depend upon its length. It has been seen that in the great majority of the cases examined the artery was short, varying from an inch to an inch and a half; in these cases the artery is deeply seated in the pelvis; when, on the contrary, the vessel is longer, it is found partly above that cavity. If the artery is very short, as occasionally happens, it would be preferable to apply a ligature to the common iliac or upon the external and internal iliacs at their origin.

Probably a better method of tying the internal iliac artery is by an abdominal section in the median line and reaching the vessel through the peritoneal cavity. This plan has been advocated by Dennis of New York on the following grounds: (1) It no way increases the danger of the operation; (2) it prevents a series of accidents which have occurred during ligation of the artery by the older methods; (3) it enables the surgeon to ascertain the exact extent of disease in the main arterial trunk, and select his spot for the application of the ligature; and (4) it occupies much less time.

Collateral Circulation.—In Professor Owen’s dissection of a case in which the internal iliac artery had been tied by Stevens ten years before death for aneurism of the sciatic artery, the internal iliac was found impervious for about an inch above the point where the ligature had been applied, but the obliteration did not extend to the origin of the external iliac, as the iliolumbar artery arose just above this point. Below the point of obliteration the artery resumed its natural diameter, and continued so for half an inch, the obturator, lateral sacral, and gluteal arising in succession from the latter portion. The obturator artery was entirely obliterated. The lateral sacral artery was as large as a crow’s quill, and had a very fine Anastomosis with the artery of the opposite side and with the middle sacral artery. The sciatic artery was entirely obliterated as far as its point of connection with the aneurismal tumor, but on the distal side of the same it was continued down along the back of the thigh nearly as large in size as the femoral, being pervious about an inch below the sac by receiving an anastomosing vessel from the profunda. The circulation was carried on by the anastomoses of the uterine and ovarian arteries;

The **superior vesical** is that part of the foetal hypogastric artery which remains pervious after birth. It extends to the side of the bladder, distributing numerous branches to the apex and body of the organ. From one of these a slender vessel is derived which accompanies the vas deferens in its course to the testis, where it anastomoses with the spermatic artery. This is the *artery of the vas deferens*. Other branches supply the ureter.

The **middle vesical**, usually a branch of the superior, is distributed to the base of the bladder and under surface of the vesiculæ seminales.

The **inferior vesical** arises from the anterior division of the internal iliac, frequently in common with the middle haemorrhoidal, and is distributed to the base of the bladder, the prostate gland, and vesiculæ seminales. The branches distributed to the prostate communicate with the corresponding vessel of the opposite side.

The **middle haemorrhoidal artery** usually arises together with the preceding vessel. It supplies the rectum, anastomosing with the other haemorrhoidal arteries.

The **uterine artery** passes inward from the anterior trunk of the internal iliac to the neck of the uterus. Ascending, in a tortuous course on the side of this viscus, between the layers of the broad ligament, it distributes branches to its substance, anastomosing near its termination, with a branch from the ovarian artery. Branches from this vessel are also distributed to the bladder and ureter.

The **vaginal artery** is analogous to the inferior vesical in the male; it descends upon the vagina, supplying its mucous membrane, and sending branches to the neck of the bladder and contiguous part of the rectum.

The **Obturator Artery** usually arises from the anterior trunk of the internal iliac, frequently from the posterior. It passes forward, below the brim of the pelvis, to the upper part of the obturator foramen, and, escaping from the pelvic cavity through a short canal formed by a groove on the under surface of the horizontal ramus of the os pubis and the arched border of the obturator membrane, it divides into an internal and external branch. In the pelvic cavity this vessel lies upon the pelvic fascia, beneath the peritoneum, and a little below the obturator nerve.

**Branches.** — Within the pelvis, the obturator artery gives off an *iliac branch* to the iliac fossa, which supplies the bone and the iliacus muscle, and anastomoses with the ilio-lumbar artery; a *vesical branch*, which runs backward to supply the bladder; and a *pubic branch*, which is given off from the vessel just before it leaves the pelvic cavity. This branch ascends upon the back of the os pubis,
communicating with offsets from the deep epigastric artery and with the corresponding vessel of the opposite side. This branch is placed on the inner side of the femoral ring. External to the pelvis, the obturator artery divides into an internal and an external branch, which are deeply situated beneath the Obturator externus muscle.

The internal branch curves downward along the inner margin of the obturator foramen, distributing branches to the Obturator externus muscle, Pectineus, Adductors, and Gracilis, and anastomoses with the external branch and with the internal circumflex artery.

The external branch curves round the outer margin of the foramen to the space between the Gemellus inferior and Quadratus femoris, where it anastomoses with the sciatic artery. It supplies the Obturator muscles, anastomoses, as it passes backward, with the internal branch and with the internal circumflex, and sends a branch to the hip-joint through the cotyloid notch, which ramifies on the round ligament as far as the head of the femur.

Peculiarities.—In two out of every three cases the obturator arises from the internal iliac, in one case in three and a half from the epigastric; and in about two and a half in seventy-two cases by two roots from both vessels. It arises in one and two-tenths per cent. from the external iliac artery. The origin of the obturator from the epigastric is not commonly found on both sides of the same body.

When the obturator artery arises at the front of the pelvis from the epigastric, it descends almost vertically to the upper part of the obturator foramen. The artery in this course usually lies in contact with the external iliac vein and on the outer side of the femoral ring (Fig. 373, A); in such cases it would not be endangered in the operation for femoral hernia. Occasionally, however, it curves inward along the free margin of Gimbernat's ligament (Fig. 373, B), and under such circumstances would almost completely encircle the neck of a hernial sac (supposing a hernia to exist in such a case), and would be in great danger of being wounded if an operation was performed.

The internal pudic is the smaller of the two terminal branches of the anterior trunk of the internal iliac, and supplies the external organs of generation. Though the course of the artery is the same in the two sexes, the vessel is much smaller in the female than in the male, and the distribution of its branches somewhat different. The description of its arrangement in the male will first be given, and subsequently the differences which it presents in the female will be mentioned.

The Internal Pudic Artery in the Male passes downward and outward to the lower border of the great sacro-sciatic foramen, and emerges from the pelvis between the Pyriformis and Coccygeus muscles: it then crosses the spine of the ischium and re-enters the pelvis through the lesser sacro-sciatic foramen. The artery now crosses the Obturator internus muscle along the outer wall of the ischiorectal fossa, being situated about an inch and a half above the lower margin of the ischial tuberosity. It is here contained in a sheath of the obturator fascia, and gradually approaches the margin of the ramus of the ischium, along which it passes forward and upward, pierces the posterior layer of the deep perineal fascia, and runs forward along the inner margin of the ramus of the os pubis; finally, it perforates the anterior layer of the deep perineal fascia and divides into its two

---

Fig. 373.—Variations in origin and course of obturator artery.
terminal branches, the dorsal artery of the penis and the artery of the corpus cavernosum.

**Relations.**—In the first part of its course, within the pelvis, it lies in front of the Pyriformis muscle and sacral plexus of nerves, and on the outer side of the rectum (on the left side). As it crosses the spine of the ischium it is covered by the Gluteus maximus. In the pelvis it lies on the outer side of the ischio-rectal fossa, upon the surface of the Obturator internus muscle, contained in a fibrous canal formed by the obturator fascia and the falloperitoneal process of the great sacro-loaded ligament. It is accompanied by the pudic veins and the internal pudic nerve, which lies internal to it on the ischial spine.

**Peculiarities.**—The internal pudic artery is sometimes smaller than usual, or fails to give off one or two of its usual branches; in such cases the deficiency is supplied by branches derived from an additional vessel, the accessory pudic, which generally arises from the internal pudic artery before its exit from the great sacrosciatic foramen. It passes forward along the lower part of the bladder and across the side of the prostate gland to the root of the penis, where it perforates the triangular ligament and gives off the branches usually derived from the pudic artery. The deficiency most frequently met with is that in which the internal pudic ends as the artery of the bulb, the artery of the corpus cavernosum and artery dorsalis penis being derived from the accessory pudic. Or the pudic may terminate as the superficial perineal, the artery of the bulb being derived, with the other two branches, from the accessory vessel.

**Surgical Anatomy.**—The relation of the accessory pudic to the prostate gland and urethra is of the greatest interest in a surgical point of view, as this vessel is in danger of being wounded in the lateral operation of lithotomy. The student should also study the position of the internal pudic artery and its branches, when running a normal course, with regard to the same operation. The superficial and the transverse perineal arteries are, of necessity, divided in this operation, but the hemorrhage from these vessels is seldom excessive; should a ligation be required, it can readily be applied on account of their superficial position. The artery of the bulb may be divided if the incision be carried too far forward, and injury of this vessel may be attended with serious or even fatal consequences. The main trunk of the internal pudic artery may be wounded if the incision be carried too far outward; but, being bound down by the strong obturator fascia and under cover of the rami of the ischium, the accident is not very likely to occur unless the vessel runs an anomalous course.
Brances.—The branches of the internal pudic artery are—

Muscular. Transverse Perineal.
Inferior Haemorrhoidal. Artery of the Bulb.
Superficial Perineal. Artery of the Corpus Cavernosum.
Dorsal Artery of the Penis.

The muscular branches consist of two sets—one given off in the pelvis, the other as the vessel crosses the ischial spine. The former are several small offsets which supply the Levator ani, the Obturator internus, the Pyriformis, and the Coccygeus muscles. The branches given off outside the pelvis are distributed to the adjacent part of the Gluteus maximus and External rotator muscles. They anastomose with branches of the sciatic artery.

The inferior haemorrhoidal are two or three small arteries which arise from the internal pudic as it passes above the tuberosity of the ischium. Crossing the ischial fossa, they are distributed to the muscles and integument of the anal region.

The superficial perineal artery supplies the scrotum and muscles and integument of the perineum. It arises from the internal pudic in front of the preceding branches, and turns upward, crossing either over or under the Transversus perinei muscle, and runs forward, parallel to the pubic arch, in the interspace between the Accelerator urinae and Erector penis muscles, both of which it supplies, and is finally distributed to the skin and dartos of the scrotum. In its passage through the perineum it lies beneath the superficial perineal fascia.

The transverse perineal is a small branch which arises either from the internal pudic or from the superficial perineal artery as it crosses the Transversus perinei muscle. It runs transversely inward along the cutaneous surface of the Transversus perinei muscle, which it supplies, as well as the structures between the anus and bulb of the urethra, and anastomoses with the one of the opposite side.

The artery of the bulb is a large but very short vessel which arises from the internal pudic between the two layers of the deep perineal fascia, and, passing nearly transversely inward, pierces the bulb of the urethra, in which it ramifies. It gives off a small branch which descends to supply Cowper’s gland.

Surgical Anatomy.—This artery is of considerable importance in a surgical point of view, as it is in danger of being wounded in the lateral operation of lithotomy—an accident usually attended in the adult with alarming haemorrhage. The vessel is sometimes very small, occasionally wanting, or even double. It sometimes arises from the internal pudic earlier than usual, and crosses the perineum to reach the back part of the bulb. In such a case the vessel could hardly fail to be wounded in the performance of the lateral operation of lithotomy. If, on the contrary, it should arise from an accessory pudic, it lies more forward than usual and is out of danger in the operation.

The artery of the corpus cavernosum, one of the terminal branches of the internal pudic, arises from that vessel while it is situated between the crus penis and the ramus of the os pubis; piercing the crus penis obliquely, it runs forward in the centre of the corpus cavernosum, to which its branches are distributed.

The dorsal artery of the penis ascends between the crus and pubic symphysis, and, piercing the suspensory ligament, runs forward on the dorsum of the penis to the glans, where it divides into two branches which supply the glans and prepuce. On the dorsum of the penis it lies immediately beneath the integument, parallel with the dorsal vein and the corresponding artery of the opposite side with the nerve external. It supplies the integument and fibrous sheath of the corpus cavernosum, sending branches through the sheath to anastomose with the preceding vessel.

The Internal Pudic Artery in the Female is smaller than in the male. Its origin and course are similar, and there is considerable analogy in the distribution of its branches. The superficial artery supplies the labia pudendi; the artery of the bulb supplies the bulbii vestibuli and the erectile tissue of the vagina; the artery of the corpus cavernosum supplies the cavernous body of the clitoris; and the arteria dorsalis clitoridis supplies the dorsum of that organ, and terminates in the glans and in the membranous fold corresponding to the prepuce of the male.
The Sciatic Artery (Fig. 375), the larger of the two terminal branches of the anterior trunk of the internal iliac, is distributed to the muscles at the back of the pelvis. It passes down to the lower part of the great sacro-sciatic foramen behind the internal pudic artery, resting on the sacral plexus of nerves and Pyriformis muscle, and escapes from the pelvis through this foramen between the Pyriformis and Coccygeus. It then descends in the interval between the trochanter major and tuberosity of the ischium, accompanied by the sciatic nerves, and covered by the Gluteus maximus, and is continued down the back of the thigh supplying the skin, and anastomosing with branches of the perforating arteries.

Within the pelvis it distributes branches to the Pyriformis, Coccygeus, and Levator ani muscles; some hemorrhoidal branches, which supply the rectum, and occasionally take the place of the middle hemorrhoidal artery; and vesical branches to the base and neck of the bladder, vesiculae seminales, and prostate gland. External to the pelvis it gives off the following branches:

- Coccygeal.
- Inferior Gluteal.
- Comes Nervi Ischiadici.
- Muscular.
- Articular.

The coccygeal branch runs inward, pierces the great sacro-sciatic ligament, and supplies the Gluteus maximus, the integument, and other structures on the back of the coccyx.

The inferior gluteal branches, three or four in number, supply the Gluteus maximus muscle, anastomosing with the gluteal artery in the substance of the muscle.

The comes nervi ischiadici is a long, slender vessel which accompanies the great sciatic nerve for a short distance; it then penetrates it and runs in its substance to the lower part of the thigh.

The muscular branches supply the muscles on the back part of the hip, anastomosing with the gluteal, external branch of the obturator, internal and external circumflex, and superior perforating arteries.

Some articular branches are distributed to the capsule of the hip-joint.

The Ilio-lumbar Artery, given off from the posterior trunk of the internal
BRANCHES OF THE INTERNAL ILIAC.

iliac, turns upward and outward between the obturator nerve and lumbo-sacral cord, to the inner margin of the Psoas muscle, behind which it divides into a lumbar and an iliac branch.

The lumbar branch supplies the Psoas and Quadratus lumborum muscles, anastomosing with the last lumbar artery, and sends a small spinal branch through the intervertebral foramen, between the last lumbar vertebra and the sacrum, into the spinal canal, to supply the spinal cord and its membranes.

The iliac branch descends to supply the Iliacus muscle; some offsets, running between the muscle and the bone, anastomose with the iliac branch of the obturator; one of these enters an oblique canal to supply the diploë, whilst others run along the crest of the ilium, distributing branches to the Gluteal and Abdominal muscles, and anastomose in their course with the gluteal, circumflex iliac, and external circumflex arteries.

The Lateral Sacral Arteries (Fig. 372) are usually two in number on each side, superior and inferior.

The superior, which is of large size, passes inward, and, after anastomosing with branches from the middle sacral, enters the first or second sacral foramen, is distributed to the contents of the sacral canal in the same manner as the lateral spinal branches from the vertebral, and, escaping by the corresponding posterior sacral foramen, supplies the skin and muscles on the dorsum of the sacrum, anastomosing with the gluteal.

The inferior passes obliquely across the front of the Pyriformis muscle and sacral nerves to the inner side of the anterior sacral foramina, descends on the front of the sacrum, and anastomoses over the coccyx with the sacral media and opposite lateral sacral arteries. In its course it gives off branches which enter the anterior sacral foramina; these, after giving off branches to be distributed to the contents of the sacral canal in the same manner as the lateral spinal branches from the vertebral, escape by the posterior sacral foramina, and are distributed to the muscles and skin on the dorsal surface of the sacrum, anastomosing with the gluteal.

The Gluteal Artery is the largest branch of the internal iliac, and appears to be the continuation of the posterior division of that vessel. It is a short, thick trunk, which passes out of the pelvis above the upper border of the Pyriformis muscle, and immediately divides into a superficial and deep branch. Within the pelvis it gives off a few muscular branches to the Iliacus, Pyriformis, and Obturator internus, and, just previous to quitting that cavity, a nutrient artery, which enters the ilium.

The superficial branch passes beneath the Gluteus maximus and divides into numerous branches, some of which supply that muscle, whilst others perforate its tendinous origin, and supply the integument covering the posterior surface of the sacrum, anastomosing with the posterior branches of the sacral arteries.

The deep branch runs between the Gluteus medius and minimus, and subdivides into two. Of these, the superior division, continuing the original course of the vessel, passes along the upper border of the Gluteus minimus to the anterior superior spine of the ilium, anastomosing with the circumflex iliac and ascending branches of the external circumflex artery. The inferior division crosses the Gluteus minimus obliquely to the trochanter major, distributing branches to the Glutei muscles, and inosculates with the external circumflex artery. Some branches pierce the Gluteus minimus to supply the hip-joint.

Surface Marking.—The position of the three main branches of the internal iliac, the sciatic, internal pudic, and gluteal, which may occasionally be the object of surgical interference, is indicated on the surface in the following way: A line is to be drawn from the posterior superior iliac spine to the posterior superior angle of the great trochanter, with the limb slightly flexed and rotated inward: the point of emergence of the gluteal artery from the upper part of the sciatic notch will correspond with the junction of the upper with the middle third of this line. A second line is to be drawn from the same point to the middle of the tuberosity of the ischium; the junction of the lower with the middle third marks the point of emergence of the sciatic and pudic arteries from the great sciatic notch.
Surgical Anatomy.—Any of these three vessels may require ligaturing for a wound or for aneurism, which is generally traumatic, and the operation may be performed by an incision, three or four inches long, in the direction of the fibres of the Glutens maximus muscle, the middle of the cut corresponding to the point indicating their respective positions.

The External Iliac Artery (Fig. 372).

The external iliac artery is larger in the adult than the internal iliac, and passes obliquely downward and outward along the inner border of the Psoas muscle, from the bifurcation of the common iliac to Poupart’s ligament, where it enters the thigh and becomes the femoral artery.

Relations.—In front, with the peritoneum, subperitoneal areolar tissue, the intestines, ileum on right side, sigmoid flexure on left, and a thin layer of fascia derived from the iliac fascia, which surrounds the artery and vein. At its origin it is occasionally crossed by the ureter. The spermatic vessels descend for some distance upon it near its termination, and it is crossed in this situation by the genital branch of the genito-crural nerve and the circumflex iliac vein; the vas deferens curves down along its inner side. Behind, it is in relation with the external iliac vein, which, at Poupart’s ligament, lies at its inner side. Externally, it rests against the Psoas muscle, from which it is separated by the iliac fascia. The artery rests upon this muscle, near Poupart’s ligament, similarly separated by the fascia. Numerous lymphatic vessels and glands are found lying on the front and inner side of the vessel.

Surface Marking.—The surface line indicating the course of the external iliac artery has been already given (see page 619).

Surgical Anatomy.—The application of a ligature to the external iliac may be required in cases of aneurism of the femoral artery or for a wound of the artery. This vessel may be secured in any part of its course, excepting near its upper end, which is to be avoided on account of the proximity of the great stream of blood in the internal iliac, and near its lower end, which should also be avoided, on account of the proximity of the epigastric and circumflex iliac vessels. One of the chief points in the performance of the operation is to secure the vessel without injury to the peritoneum. The patient having been placed in the recumbent position, an incision should be made, commencing below at a point about three-quarters of an inch above Poupart’s ligament, and a little external to its middle, and running upward and outward, parallel to Poupart’s ligament, to a point above the anterior superior spine of the ilium. When the artery is deeply seated more room will be required, and may be obtained by curving the incision from the point last named inward toward the umbilicus for a short distance, or, if the lower part of the artery is to be reached, the surgeon may adopt the plan advocated by Sir Astley Cooper, by making an incision close to Poupart’s ligament from about half an inch outside of the external abdominal ring to one inch internal to the anterior superior spine of the ilium. This incision, being made in the course of the fibres of the aponeurosis of the external oblique, is less likely to be followed by a ventral hernia, but there is danger of wounding the epigastric artery. Abernethy, who first tied this artery, made his incision in the course of the vessel. The abdominal muscles and transversalis fascia having been cautiously divided, the peritoneum should be separated from the iliac fossa and raised toward the pelvis; and on introducing the finger to the bottom of the wound the artery may be felt pulsating along the inner border of the Psoas muscle. The external iliac vein is generally found on the inner side of the artery,
and must be cautiously separated from it by the finger-nail or handle of the knife, and the aneurism needle should be introduced on the inner side, between the artery and the vein.

Ligature of the external iliac artery has recently been performed in three or more cases by a transperitoneal method. An incision four inches in length is made in the semilunar line, commencing about an inch below the umbilicus and carried through the abdominal wall into the peritoneal cavity. The intestines are then pushed upward and held out of the way by a broad abdominal retractor, and an incision made through the peritoneum at the margin of the pelvis in the course of the artery, and the vessel secured in any part of its course which may seem desirable to the operator. The advantages of this operation appear to be that if it is found necessary the common iliac artery can be ligatured instead of the external iliac without extension or modification of the incision; and secondly, that the vessel can be ligatured without in any way interfering with the coverings of the sac. Possibly a disadvantage may exist in the greater risk of hernia after this method.

Collateral Circulation.—The principal anastomoses in carrying on the collateral circulation, after the application of a ligation to the external iliac, are—the ilio-lumbar with the circumflex iliac; the gluteal with the external circumflex; the obturator with the internal circumflex; the sciotic with the superior perforating and circumflex branches of the profunda artery; and the internal pudic with the external pudic. When the obturator arises from the epigastric, it is supplied with blood by branches, either from the internal iliac, the lateral sacral, or the internal pudic. The epigastric receives its supply from the internal mammary and inferior intercostal arteries, and from the internal iliac by the anastomoses of its branches with the obturator.

In the dissection of a limb eighteen years after the successful ligation of the external iliac artery by Sir A. Cooper, which is to be found in Guy's Hospital Reports, vol. i. p. 50, the anastomosing branches are described in three sets: An anterior set.—1. a very large branch from the ilio-lumbar artery to the circumflex iliac; 2. another branch from the ilio-lumbar, joined by one from the obturator, and breaking up into numerous tortuous branches to anastomose with the external circumflex; 3. two other branches from the obturator, which passed over the brim of the pelvis, communicated with the epigastric, and then broke up into a plexus to anastomose with the internal circumflex. An internal set.—Branches given off from the obturator, after quitting the pelvis, which ramified among the adductor muscles on the inner side of the hip-joint, and joined most freely with branches of the internal circumflex. A posterior set.—1. three large branches from the gluteal to the external circumflex; 2. several branches from the sciatic around the great sciatic notch to the internal and external circumflex, and the perforating branches of the profunda.

Branches.—Besides several small branches to the Psoas muscle and the neighboring lymphatic glands, the external iliac gives off two branches of considerable size—the Deep Epigastric and Deep Circumflex Iliac.

The Deep Epigastric Artery arises from the external iliac a few lines above Poupart's ligament. It at first descends to reach this ligament, and then ascends obliquely along the inner margin of the internal abdominal ring, lying between the transversalis fascia and peritoneum, and, continuing its course upward, it pierces the transversalis fascia, and, passing over the semilunar fold of Douglas, enters the sheath of the Rectus muscle. It then ascends on the posterior surface of the muscle, and finally divides into numerous branches, which anastomose, above the umbilicus, with the terminal branches of the internal mammary and inferior intercostal arteries. The deep epigastric artery bears a very important relation to the internal abdominal ring as it passes obliquely upward and inward from its origin from the external iliac. In this part of its course it lies along the lower and inner margin of the ring and beneath the commencement of the spermatic cord. As it winds round the internal abdominal ring it is crossed by the vas deferens in the male and the round ligament in the female.

Branches.—The branches of this vessel are the following: The cremasteric, which accompanies the spermatic cord, and supplies the Cremaster muscle and other coverings of the cord, anastomosing with the spermatic artery; a pubic branch, which runs along Poupart's ligament, and then descends behind the pubes to the inner side of the femoral ring, and anastomoses with offsets from the obturator artery; muscular branches, some of which are distributed to the abdominal muscles and peritoneum, anastomosing with the lumbar and circumflex iliac arteries; others perforate the tendon of the External oblique, and supply the integument, anastomosing with branches of the superficial epigastric.
Peculiarities.—The origin of the epigastric may take place from any part of the external iliac between Poupart’s ligament and two inches and a half above it, or it may arise below this ligament, from the femoral or from the deep femoral.

Union with Branches.—It frequently arises from the external iliac by a common trunk with the obturator. Sometimes the epigastric arises from the obturator, the latter vessel being furnished by the internal iliac, or the epigastric may be formed of two branches, one derived from the external iliac, the other from the internal iliac.

Surgical Anatomy.—The deep epigastric artery follows a line drawn from the middle of Poupart’s ligament toward the umbilicus; but shortly after this line crosses the linea semilunaris the direction changes, and the course of the vessel is directly upward in the line of junction of the inner third with the outer two-thirds of the Rectus muscle. It has important surgical relations, in addition to the fact that it is one of the principal means, through its anastomosis with the internal mammary, in establishing the collateral circulation after ligature of either the common or external iliac arteries. It lies close to the internal abdominal ring, and is therefore internal to an oblique inguinal hernia, but external to a direct inguinal hernia, as it emerges from the abdomen. It forms the outer boundary of Hesselbach’s triangle. It is in close relationship with the spermatic cord, which lies in front of it in the inguinal canal, separated only by the transversalis fascia. The vas deferens hooks round its outer side.

The Deep Circumflex Iliac Artery arises from the outer side of the external iliac nearly opposite the epigastric artery. It ascends obliquely outward behind Poupart’s ligament, contained in a fibrous sheath formed by the junction of the transversalis and iliac fasciae, to the anterior superior spinoous process of the ilium. It then runs along the inner surface of the crest of the ilium to about its middle, where it pierces the Transversalis, and runs backward between that muscle and the Internal oblique, to anastomose with the ilio-lumbar and gluteal arteries. Opposite the anterior superior spine of the ilium it gives off a large branch, which ascends between the Internal oblique and Transversalis muscles, supplying them, and anastomosing with the lumbar and epigastric arteries.

**ARTERIES OF THE LOWER EXTREMITY.**

**The Femoral Artery** (Fig. 376).

The femoral artery is the continuation of the external iliac. It commences immediately behind Poupart’s ligament, midway between the anterior superior spine of the ilium and the symphysis pubis, and, passing down the fore part and inner side of the thigh, terminates at the opening in the Adductor magnus, at the junction of the middle with the lower third of the thigh, where it becomes the popliteal artery. The vessel, at the upper part of thigh, lies a little internal to the head of the femur; in the lower part of its course, on the inner side of the shaft of the bone, and between these two parts the vessel is far away from the bone. In the upper third of the thigh it is contained in a triangular space called Scarpa’s triangle. In the middle third of the thigh it is contained in an aponeurotic canal called Hunter’s canal.

**Scarpa’s Triangle.**—Scarpa’s triangle corresponds to the depression seen immediately below the fold of the groin. It is a triangular space, the apex of which is directed downward, and the sides formed externally by the Sartorius, internally by the Adductor longus, and above by Poupart’s ligament. The floor of the space is formed from without inward by the Iliacus, Psoas, Pectineus, a small part of the Adductor brevis and the Adductor longus muscles; and it is divided into two nearly equal parts by the femoral vessels, which extend from the middle of its base to its apex, the artery giving off in this situation its cutaneous and profunda branches, the vein receiving the deep femoral and internal saphenous. On the outer side of the femoral artery is the anterior crural nerve dividing into its branches. Besides the vessels and nerves, this space contains some fat and lymphatics.

**Hunter’s Canal.**—This is the aponeurotic space in the middle third of the thigh, extending from the apex of Scarpa’s triangle to the femoral opening in the Adductor magnus muscle. It is bounded, externally, by the Vastus internus; postero-internally by the Adductor longus and magnus; and antero-internally by a strong aponeurosis which extends transversely from the Vastus internus, across
the femoral vessels to the Adductor longus and magnus muscles, lying on which aponeurosis is the Sartorius muscle. It contains the femoral artery and vein enclosed in their own sheath of areolar tissue, the vein being behind and on the outer side of the artery, and the internal or long saphenous nerve lying on the outer side of the vessels.

For convenience of description, and also in reference to its surgical anatomy, the femoral artery is divided into a short trunk, about an inch and a half or two inches long, which is known as the common femoral artery, and the remainder of the vessel, which is known as the superficial femoral, to distinguish it from the deep femoral (profunda femoris), which is a large branch given off from the common femoral at its termination, and which by its derivation from the parent trunk marks the commencement of the superficial femoral artery.

The common femoral artery is very superficial, being covered by the skin and superficial fascia, superficial inguinal lymphatic glands, the iliac portion of the fascia lata, and the prolongation downward of the Transversalis fascia, which forms the sheath of the vessels. It has in front of it filaments from the crural branch of the genitocrural nerve, the superficial circumflex iliac vein, and occasionally the superficial epigastric vein. It rests on the inner margin of the Psoas muscle, which separates it from the capsular ligament of the hip-joint, and a little lower on the Pectineus muscle; and crossing behind it is the branch to the Pectineus from the anterior crural nerve. Separating the artery from the Psoas and Pectineus muscles is the pubic portion of the fascia lata and the prolongation from the fascia covering the Iliacus muscle, which forms the posterior layer of the sheath of the vessels. The anterior crural nerve lies about half an inch to the outer side of the common femoral artery, lying between the Psoas and Iliacus muscles. To the inner side of the artery is the femoral vein, between the margins of the Pectineus and Psoas muscles. The two vessels are enclosed in a strong fibrous sheath formed by the proper sheath of the vessels strengthened by the fascia lata (see page 507); the
artery and vein are separated, however, from one another by a thin fibrous partition.

**Plan of Relations of the Common Femoral Artery.**

*In front.*

The superficial femoral artery is only superficial where it lies in Scarpa's triangle. Here it is covered by the skin, superficial and deep fascia, and crossed by the internal cutaneous branch of the anterior crural nerve. In Hunter's canal it is more deeply seated, being covered by the integument, the superficial and deep fascia, the Sartorius and aponeurotic covering of Hunter's canal. The internal saphenous nerve crosses the artery from without inward. Behind, the artery lies at its upper part on the femoral vein and the profunda artery and vein, which separate it from the Pectineus muscle, and lower down on the Adductor longus and Adductor magnus muscles. To the outer side is the long saphenous nerve and the nerve to the Vastus internus, the Vastus internus muscle, and, at its lower part, the femoral vein. To the inner side is the Adductor longus above and the Adductor magnus and Sartorius below.

- Adductor longus.
- Adductor magnus.

The femoral vein, at Poupart's ligament, lies close to the inner side of the artery, separated from it by a thin fibrous partition; but lower down it is behind it, and then to its outer side.

The internal saphenous nerve is situated on the outer side of the artery, in the
middle third of the thigh, beneath the aponeurotic covering of Hunter's canal, but not usually within the sheath of the vessels. The internal cutaneous nerve passes obliquely across the upper part of the sheath of the femoral artery.

Peculiarities.—Double Femoral reunited.—Several cases are recorded in which the femoral artery divided into two trunks below the origin of the profunda, and became reunited near the opening in the Adductor magnus so as to form a single popliteal artery. One of them occurred in a patient operated upon for popliteal aneurism.

Change of Position.—A few cases have been recorded in which the femoral artery was situated at the back of the thigh, the vessel being continuous above with the internal iliac, escaping from the pelvis through the great sacro-iliac foramen, and accompanying the great sciatic nerve to the popliteal space, where its division occurred in the usual manner. The external iliacs in these cases was small, and terminated in the profunda.

Position of the Vein.—The femoral vein is occasionally placed along the inner side of the artery, throughout the entire extent of Scarpa's triangle. It may be slit so that a large vein is placed on each side of the artery for a greater or less extent.

Origin of the Profunda.—This vessel occasionally arises from the inner side, and, more rarely, from the back of the common trunk; but the more important peculiarity, in a surgical point of view, is that which relates to the height at which the vessel arises from the femoral. In three-fourths of a large number of cases it arose between one or two inches below Poupart's ligament; in a few cases the distance was less than an inch; more rarely, opposite the ligament; and in one case, above Poupart's ligament, from the external iliac. Occasionally, the distance between the origin of the vessel and Poupart's ligament exceeds two inches, and in one case it was found to be as much as four inches.

Surface Marking.—The upper two-thirds of a line drawn from a point midway between the anterior superior spine of the ilium and the symphysis pubis to the prominent tuberosity on the inner condyle of the femur, with the thigh abducted and rotated outward, will indicate the course of the femoral artery.

Surgical Anatomy.—Compression of the femoral artery, which is constantly requisite in amputations and other operations on the lower limb, and also for the cure of popliteal aneurism, is most effectually made immediately below Poupart's ligament. In this situation the artery is very superficial, and is merely separated from the horizontal ramus of the os pubis by the Psoas muscle; so that the surgeon, by means of his thumb or a compressor, may effectually control the circulation through it. This vessel may also be compressed in the middle third of the thigh by placing a compressor over the artery, beneath the tourniquet, and directing the pressure from within outward, so as to compress the vessel against the inner side of the shaft of the femur.

The application of a ligature to the femoral artery may be required in the cases of wound or aneurism of the arteries of the leg, of the popliteal or femoral; and the vessel may be exposed and tied in any part of its course. The great depth of this vessel at its lower part, its close connection with important structures, and the density of its sheath render the operation in this situation one of much greater difficulty than the application of a ligature at its upper part, where it is more superficial.

Ligature of the common femoral artery is usually considered unsafe, on account of the connection of large branches with it—viz., the deep epigastric and the deep circumflex iliac arising just above Poupart's ligament; on account of the number of small branches which arise from it in its short course; and on account of the uncertainty of the origin of the profunda femoris, which, if it arise high up, would be too close to the ligature for the formation of a firm coagulum. The profunda sometimes arises higher than the point above mentioned, and rarely between two or three inches (in one case four) below Poupart's ligament. It would appear, then, that the most favorable situation for the application of a ligature to the femoral is between four and five inches from its point of origin. In order to expose the artery in this situation, an incision between two and three inches long should be made in the course of the vessel, the patient lying in the recumbent position, with the limb slightly flexed and abducted. A large vein is frequently met with. passing in the course of the artery to join the saphena; this must be avoided, and the fascia lata having been cautiously divided and the Sartorius exposed, that muscle must be drawn outward in order to fully expose the sheath of the vessels. The finger being introduced into the wound and the pulsation of the artery felt, the sheath should be opened on the outer side of the vessel to a sufficient extent to allow of the introduction of the ligature, but no farther; otherwise the nutrition of the coats of the vessel may be interfered with, or muscular branches which arise from the vessel at irregular intervals may be divided. In this part of the operation the long saphenous nerve and the nerve to the Vastus internus, which is in close relation with the sheath, should be avoided. The aneurism needle must be carefully introduced and kept close to the artery, to avoid the femoral vein, which lies behind the vessel in this part of its course.

To expose the artery, in Hunter's canal, an incision should be made through the integument, between three and four inches in length, a finger's breadth internal to the line of the artery, in the middle of the thigh—i. e. midway between the groin and the knee. The fascia lata having been divided and the Sartorius muscle exposed, it should be drawn inward, when the strong

1 Ligature of the femoral artery has been also recommended and performed for elephantiasis of the leg and acute inflammation of the knee-joint (Mauder, Clin. Soc. Trans., vol. ii. p. 37).
fascia which is stretched across from the Adductors to the Vastus internus will be exposed, and must be freely divided; the sheath of the vessels is now seen, and must be opened, and the artery secured by passing the aneurism needle between the vein and artery in the direction from without inward. The femoral vein in this situation lies on the outer side of the artery, the long saphenous nerve on its anterior and outer side.

It has been seen that the femoral artery occasionally divides into two trunks below the origin of the profunda. If in the operation for tying the femoral two vessels are met with, the surgeon should alternately compress each, in order to ascertain which vessel is connected with the aneurismal tumor or with the bleeding from the wound, and that one only should be tied which controls the pulsation or hemorrhage. If, however, it is necessary to compress both vessels before the circulation in the tumor is controlled, both should be tied, as it would be probable that they are both aneurismal, as in the instances referred to above.

In wounds of the femoral artery the question of the mode of treatment is of considerable importance. If the wound in the superficial structures is a large one, the injured vessel must be exposed and tied; but if the wound is a punctured one and the bleeding has ceased, the question will arise whether to cut down upon the artery or to trust to pressure. Mr. Cripps advises that if the wound is in the "upper part of the thigh—that is to say, in a position where the femoral artery is comparatively superficial—the surgeon may enlarge the opening with a good prospect of finding the wounded vessel without an extensive or prolonged operation. If the wound be in the lower half of the thigh, owing to the greater depth of the artery and the possibility of its being the popliteal that is wounded, the search is rendered a far more severe and hazardous operation, and it should not be undertaken until a thorough trial of pressure has proved ineffectual."

Great care and attention are necessary for the successful application of pressure. The limb should be carefully bandaged from the foot upward to the wound, which is not covered, and then onward to the groin. The wound is then dusted with iodiform or boracic powder and a conical pad applied over the wound. Rollers the thickness of the index finger are then placed along the course of the vessel above and below the wound, and the whole carefully bandaged to a back splint with a foot-piece.

Collateral Circulation.—When the common femoral is tied the main channels for carrying on the circulation are the anastomoses of the gluteal and circumflex iliac arteries above with the external circumflex below; of the obturator and sciatic above with the internal circumflex below; and of the common nerve included with the arteries in the ham.

The principal agents in carrying on the collateral circulation after ligation of the superficial femoral artery are, according to Sir A. Cooper, as follows:

"The arteria profunda formed the new channel for the blood," "The first artery sent off passed down close to the back of the thigh-bone, and entered the two superior articular branches of the popliteal artery."

"The second new large vessel, arising from the profunda at the same part with the former, passed down by the inner side of the Biceps muscle to a branch of the popliteal which was distributed to the Gastrocnemius muscle; whilst a third artery, dividing into several branches, passed down with the sciatic nerve behind the knee-joint, and some of its branches united themselves with the inferior articular arteries of the popliteal, with some recurrent branches of those arteries, others passing to the Gastrocnemii, and, lastly, with the origin of the anterior and posterior tibial arteries."

"It appears, then, that it is those branches of the profunda which accompany the sciatic nerve that are the principal supporters of the new circulation."

In Porta's work 3 (tab. xii., xiii.) is a good representation of the collateral circulation after the ligation of the femoral artery. The patient had survived the operation three years. The lower part of the artery is at least as large as the upper; about two inches of the vessel appear to have been obliterated. The external and internal circumflex arteries are seen anastomosing by a great number of branches with the lower branches of the femoral (muscular and anastomotica magna) and with the articular branches of the popliteal. The branches from the external circumflex are extremely large and numerous. One very distinct anastomosis can be traced between this artery on the outside and the anastomotica magna on the inside through the intervention of the superior external articular artery, with which they both anastomose; and blood reaches even the anterior tibial recurrent from the external circumflex by means of anastomosis with the same external articular artery. The perforating branches of the profunda are also seen bringing blood round the obliterated portion of the artery into long branches (muscular) which have been given off just below that portion. The termination of the profunda itself anastomoses most freely with the superior external articular. A long branch of anastomosis is also traced down from the internal iliac by means of the comes nervi ischiadicii of the sciatic, which anastomoses on the popliteal nerves with branches from the popliteal and posterior tibial arteries. In this case the anastomosis had been too free, since the pulsation and growth of the aneurism recurred, and the patient died after ligation of the external iliac.

There is an interesting preparation in the Museum of the Royal College of Surgeons of a limb on which John Hunter had tied the femoral artery fifty years before the patient's death. The whole of the superficial femoral and popliteal artery seems to have been obliterated. The

---

3 Alterazioni patologiche delle Articoli.
anastomosis by means of the comities ischiadici, which is shown in Porta’s plate, is distinctly seen: the external circumflex and the termination of the profunda artery, seem to have been the chief channels of anastomosis; but the injection has not been a very successful one.

**Branches.**—The branches of the femoral artery are—

**Anastomotica Magna.**

The **superficial epigastric** arises from the femoral about half an inch below Poupart’s ligament, and, passing through the saphenous opening in the fascia lata, ascends on the abdomen, in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches to the superficial inguinal glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric.

The **superficial circumflex iliac** is the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outward, parallel with Poupart’s ligament, as far as the crest of the ilium, dividing into branches which supply the integument of the groin, the superficial fascia, and the superficial inguinal lymphatic glands, anastomosing with the circumflex iliac and with the gluteal and external circumflex arteries.

The **superficial external pudic** (superior) arises from the inner side of the femoral artery, close to the preceding vessels, and, after passing through the saphenous opening, courses inward, across the spermatic cord or round ligament, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male, and the labium in the female, anastomosing with branches of the internal pudic.

The **deep external pudic** (inferior), more deeply seated than the preceding, passes inward on the Pectineus muscle, covered by the fascia lata, which it pierces at the inner border of the thigh, its branches being distributed, in the male, to the integument of the scrotum and perinaeum; and in the female, to the labium, anastomosing with branches of the superficial perineal artery.

The **Profunda Femoris** (deep femoral artery) nearly equals the size of the superficial femoral. It arises from the outer and back part of the femoral artery, from one to two inches below Poupart’s ligament. It at first lies on the outer side of the superficial femoral, and then passes behind it and the femoral vein to the inner side of the femur, and, passing downward beneath the Adductor longus, terminates at the lower third of the thigh in a small branch which pierces the Adductor magnus (and from this circumstance is sometimes called the fourth perforating artery), and is distributed to the flexor muscles on the back of the thigh, anastomosing with branches of the popliteal and inferior perforating arteries.

**Relations.**—**Behind,** it lies first upon the Iliacus, and then on the Pectineus, Adductor brevis, and Adductor magnus muscles. **In front,** it is separated from the femoral artery, above by the femoral and profunda veins, and below by the Adductor longus. **On its outer side** the origin of the Vastus internus separates it from the femur.

**THE FEMORAL ARTERY.** 635

Adductor magnus.

The External Circumflex Artery supplies the muscles on the front of the thigh. It arises from the outer side of the profunda, passes horizontally outward, between the divisions of the anterior crural nerve and behind the Sartorius and Rectus muscles, and divides into three sets of branches—ascending, transverse, and descending.

The ascending branches pass upward, beneath the Tensor vaginae femoris muscle, to the outer side of the hip, anastomosing with the terminal branches of the gluteal and circumflex iliac arteries.

The descending branches, three or four in number, pass downward, behind the Rectus, upon the Vasti muscles, to which they are distributed, one or two passing beneath the Vastus externus as far as the knee, anastomosing with the superior articular branches of the popliteal artery. These are accompanied by the branch of the anterior crural nerve to the Vastus externus.

The transverse branches, the smallest and least numerous, pass outward over the Crureus, pierce the Vastus externus, and wind round the femur to its back part, just below the great trochanter, anastomosing at the back of the thigh with the internal circumflex, sciatic, and superior perforating arteries.

The Internal Circumflex Artery, smaller than the external, arises from the inner and back part of the profunda, and winds round the inner side of the femur, between the Pectineus and Psoas muscles. On reaching the upper border of the Adductor brevis it gives off two branches, one of which passes inward to be distributed to the Adductor muscles, the Gracilis, and Obturator externus, anastomosing with the obturator artery; the other descends, and passes beneath the Adductor brevis, to supply it and the great Adductor; while the continuation of the vessel passes backward, between the Quadratus femoris and upper border of the Adductor magnus, anastomosing with the sciatic, external circumflex, and superior perforating arteries ("the crucial anastomosis"). Opposite the hip-joint this branch gives off an articular vessel, which enters the joint beneath the transverse ligament, and, after supplying the adipose tissue, passes along the round ligament to the head of the bone.

The Perforating Arteries (Fig. 375), usually three in number, are so called from their perforating the tendon of the Adductor magnus muscle to reach the back of the thigh. The first is given off above the Adductor brevis, the second in front of that muscle, and the third immediately below it.

The first or superior perforating artery passes backward between the Pectineus and Adductor brevis (sometimes perforates the latter); it then pierces the Adductor magnus close to the linea aspera, and divides into branches which supply the Adductor brevis, the Adductor magnus, the Biceps, and Gluteus maximus muscles, anastomosing with the sciatic, internal and external circumflex, and middle perforating arteries.

The second or middle perforating artery, larger than the first, pierces the tendons of the Adductor brevis and Adductor magnus muscles, and divides into ascending and descending branches, which supply the flexor muscles of the thigh,
anastomosing with the superior and inferior perforating. The nutrient artery of the femur is usually given off from this branch.

The third or inferior perforating artery is given off below the Adductor brevis; it pierces the Adductor magnus, and divides into branches which supply the flexor muscles of the thigh, anastomosing above with the perforating arteries, and below with the terminal branches of the profunda and the muscular branches of the popliteal.

Muscular branches are given off from the superficial femoral throughout its entire course. They vary from two to seven in number, and supply chiefly the Sartorius and Vastus internus. The Anastomotica Magna arises from the femoral artery just before it passes through the tendinous opening in the Adductor magnus muscle, and divides into a superficial and deep branch.

The superficial branch accompanies the long saphenous nerve beneath the Sartorius, and, piercing the fascia lata, is distributed to the integument. The deep branch descends in the substance of the Vastus internus, lying in front of the tendon of the Adductor magnus, to the inner side of the knee, where it anastomoses with the superior internal articular artery and anterior recurrent branch of the anterior tibial. A branch from this vessel crosses outward above the articular surface of the femur, forming an anastomotic arch with the superior external articular artery, and supplies branches to the knee-joint.

**Popliteal Artery.**

The popliteal artery commences at the termination of the femoral at the opening in the Adductor magnus, and, passing obliquely downward and outward behind the knee-joint to the lower border of the Popliteus muscle, divides into the anterior and posterior tibial arteries. A portion of the artery lies in the popliteal space; but above, to a slight extent, and below, to a considerable extent, it is covered by the muscles which form the boundaries of the space, and is therefore beyond the confines of the hollow.

**THE POPLITEAL SPACE** (Fig. 377).

Dissection.—A vertical incision about eight inches in length should be made along the back part of the knee-joint, connected above and below by a transverse incision from the inner to the outer side of the limb. The flaps of integument included between these incisions should be reflected in the direction shown in Fig. 328, page 514.

Boundaries.—The popliteal space is lozenge-shaped, widest at the back part of the knee-joint. It is bounded externally, above the joint, by the Biceps, and, below the joint, by the Plantaris and external head of the Gastrocnemius; internally, above the joint, by the Semimembranosus and Semitendinosus, the latter, however, lying on (posterior to) the former, whose edge is the real boundary; below the joint, by the inner head of the Gastrocnemius. Above, it is limited by the apposition of the inner and outer hamstring muscles; below, by the junction of the two heads of the Gastrocnemius. The floor is formed by the lower part of the posterior surface of the shaft of the femur, the posterior ligament of the knee-joint, the upper end of the tibia, and the fascia covering the Popliteus muscle, and the space is covered in by the fascia lata.

Contents.—It contains the popliteal vessels and their branches, together with the termination of the external saphenous vein, the internal and external popliteal nerves and some of their branches, the lower extremity of the small sciotic nerve, the articular branch from the obturator nerve, a few small lymphatic glands, and a considerable quantity of loose adipose tissue.

Position of Contained Parts.—The internal popliteal nerve descends in the middle line of the space, lying superficial and crossing the artery from without inward. The external popliteal nerve descends on the outer side of the space,
lying close to the tendon of the Biceps muscle. More deeply at the bottom of the space are the popliteal vessels, the vein lying superficial and a little external to the artery, to which it is closely united by dense areolar tissue; sometimes the vein is placed on the inner instead of the outer side of the artery; or the vein may be double, the artery lying between the two venæ comites, which are usually connected by short transverse branches. More deeply, and, at its upper part, close to the surface of the bone, is the popliteal artery, and passing off from it at right angles are its articular branches. The articular branch from the obturator nerve descends upon the popliteal artery to supply the knee, and occasionally there is found deep in the space an articular filament from the great sciatic nerve. The popliteal lymphatic glands, four or five in number, are found surrounding the artery: one usually lies superficial to the vessel; another is situated between it and the bone, and the rest are placed on either side of it.

The Popliteal Artery, in its course downward from the aperture in the Adductor magnus to the lower border of the Popliteus muscle, rests first on the inner surface of the femur, and is then separated by a little fat from the hollowed popliteal surface of the bone; in the middle of its course it rests on the posterior ligament of the knee-joint, and below on the fascia covering the Popliteus muscle. Superficially, it is covered above by the Semimembranosus; in the middle of its course, by a quantity of fat, which separates it from the deep fascia and integument; and below it is overlapped by the Gastrocnemius, Plantaris, and Soleus muscles, the popliteal vein, and the internal popliteal nerve. The popliteal vein, which is intimately attached to the artery, lies superficial and external to it until near the termination of the artery, when the vein crosses it and lies to its inner side. The internal popliteal nerve is still more superficial and external above, but below the joint it crosses the artery and lies on its inner side. Laterally, the artery is bounded by the muscles which are situated on either side of the popliteal space.

Peculiarities in Point of Division.—Occasionally the popliteal artery divides prematurely into its terminal branches; this unusual division occurs most frequently opposite the knee-joint.

Unusual Branches.—The artery sometimes divides into the anterior tibial and peroneal, the posterior tibial being wanting or very small. Occasionally the popliteal is found to divide into three branches, the anterior and posterior tibial and peroneal.

Surface Marking.—The course of the upper part of the popliteal artery is indicated by a line drawn from the outer border of the Semimembranosus muscle at the junction of the middle and lower third of the thigh obliquely downward to the middle of the popliteal space, exactly behind the knee-joint. From this point it passes vertically downward to the level of a line drawn through the lower part of the tubere of the tibia.

Surgical Anatomy.—The popliteal artery is not infrequently the seat of injury. It may be torn by direct violence, as by the passage of a cart-wheel over the knee or by hyper-extension of the knee; and in the dead body, at all events, the middle and internal coats may be ruptured by extreme flexion. It may also be lacerated by fracture of the lower part of the shaft of the
BRANCHES OF THE POPLITEAL ARTERY.

It has been torn in breaking down adhesions in cases of fibrous ankylosis of the knee, and is in danger of being wounded, and in fact has been wounded, in performing Macowen's operation of osteotomy of the lower end of the femur for genu valgum. In addition, Spencer records a case in which the popliteal artery was wounded from in front by a stab just below the knee, the knife passing through the interosseous space. The popliteal artery is more frequently the seat of aneurism than any other artery in the body, with the exception of the thoracic aorta. This is due no doubt, in a great measure to the amount of movement to which it is subjected, and to the fact that it is supported by loose and lax tissue only, and not by muscles, as is the case with most arteries.

Ligation of the popliteal artery is required in cases of wound of that vessel, but for aneurism of the posterior tibial it is preferable to tie the superficial femoral. The popliteal may be tied in the upper or lower part of its course; but in the middle of the ham the operation is attended with considerable difficulty, from the great depth of the artery and from the extreme degree of tension of the lateral boundaries of the space.

In order to expose the vessel in the upper part of its course the patient should be placed in the prone position, with the limb extended. An incision about three inches in length should then be made through the integument, along the posterior margin of the Semimembranosus, and, the fascia lata having been divided, this muscle must be drawn inward. The internal popliteal nerve will be first exposed, lying very superficial and external to the artery; beneath this will be seen the popliteal vein, and, still deeper and to its inner side, the artery. The vein and nerve must be cautiously separated from the artery, and the aneurism needle passed around the vessel from without inward.

To expose the vessel in the lower part of its course, where the artery lies between the two heads of the Gastrocnemius, the patient should be placed in the same position as in the preceding operation. An incision should then be made through the integument in the middle line, commencing opposite the bend of the knee-joint, care being taken to avoid the external saphenous vein and nerve. After dividing the deep fascia and separating some dense cellular membrane, the artery, vein, and nerve will be exposed, descending between the two heads of the Gastrocnemius. Some muscular branches of the popliteal should be avoided if possible, or, if divided, tied immediately. The leg being now flexed, in order the more effectually to separate the two heads of the Gastrocnemius the nerve should be drawn inward and the vein outward, and the aneurism needle passed between the artery and vein from without inward.

In cases where the artery has been wounded during an osteotomy of the lower end of the femur it would be most conveniently secured from the front at the inner side of the thigh. The knee is flexed and the limb placed on its outer side. An incision, three inches long, is made parallel to and immediately behind the tendon of the Adductor magnus from the junction of the middle and lower third of the thigh. Skin, superficial and deep fascia are to be divided, care being taken of the internal saphenous vein; the Adductor magnus is to be drawn forward and the inner hamstring tendons backward, and the artery will be found surrounded by fat. The nerve and vein are usually not seen, as they lie to the outer side of the artery.

The branches of the popliteal artery are—

Muscular

Superior.

Superior Internal Articular.

Inferior or Sural.

Azygos Articular.

Cutaneous.

Inferior External Articular.

Superior External Articular.

Inferior Internal Articular.

The superior muscular branches, two or three in number, arise from the upper part of the popliteal artery, and are distributed to the Vastus externus and flexor muscles of the thigh, anastomosing with the inferior perforating and terminal branches of the profunda.

The inferior muscular (sural) are two large branches which are distributed to the two heads of the Gastrocnemius and to the Plantaris muscle. They arise from the popliteal artery opposite the knee-joint.

Cutaneous branches descend on each side and in the middle of the limb, between the Gastrocnemius and integument; they arise separately from the popliteal artery or from some of its branches, and supply the integument of the calf.

The superior articular arteries, two in number, arise one on each side of the popliteal, and wind round the femur immediately above its condyles to the front of the knee-joint. The internal branch passes beneath the tendon of the Adductor magnus, and divides into two, one of which supplies the Vastus internus, inosculating with the anastomotica magna and inferior internal articular; the other ramifies close to the surface of the femur, supplying it and the knee-joint, and anastomosing with the superior external articular artery. The external branch passes above the outer condyle, beneath the tendon of the Biceps, and divides into
a superficial and deep branch: the superficial branch supplies the Vastus exter-

nus, and anastomoses with the descending branch of the external circumflex, and the inferior external articular arteries; the deep branch supplies the lower part
of the femur and knee-joint, and forms an anastomotic arch across the bone with the anastomotica magna and the inferior internal articular arteries.

The *azygos articular* is a small branch arising from the popliteal artery opposite the bend of the knee-joint. It pierces the posterior ligament, and supplies the ligaments and synovial membrane in the interior of the articulation.

The *inferior articular arteries*, two in number, arise from the popliteal beneath the Gastrocnemius, and wind round the head of the tibia below the joint. The *internal* one passes below the inner tuberosity, beneath the internal lateral ligament, at the anterior border of which it ascends to the front and inner side of the joint, to supply the head of the tibia and the articulation of the knee, anastomosing with the inferior external articular and superior internal articular arteries. The *external* one passes outward above the head of the fibula, to the front of the knee-joint, passing in its course beneath the outer head of the Gastrocnemius, the external lateral ligament, and the tendon of the Biceps muscle, and divides into branches which anastomose with the inferior internal articular artery, the superior external articular artery, and the anterior recurrent branch of the anterior tibial.

**Circumpatellar Anastomosis.**—Around and above the patella, and on the contiguous ends of the femur and tibia, is a large network of vessels, forming a superficial and deep plexus from which numerous offsets proceed into the interior of the joint. The arteries from which this plexus is formed are the two internal and two external articular branches of the popliteal, the anastomotica magna, the terminal branch of the profunda, the descending branch from the external circumflex, and the anterior recurrent branch of the anterior tibial.

**The Anterior Tibial Artery** (Fig. 378).

The *anterior tibial artery* commences at the bifurcation of the popliteal at the lower border of the Popliteus muscle, passes forward between the two heads of the Tibialis posticus, and through the large oval aperture above the upper border of the interosseous membrane to the deep part of the front of the leg: it then descends on the anterior surface of the interosseous membrane, gradually approaching the tibia; and at the lower part of the leg lies on this bone, and then on the anterior ligament of the ankle to the bend of the ankle-joint, where it lies more superficially, and becomes the *dorsalis pedis*.

**Relations.**—In the upper two-thirds of its extent it rests upon the interosseous membrane, to which it is connected by delicate fibrous arches thrown across it; in the lower third, upon the front of the tibia and the anterior ligament of the ankle-joint. In the upper third of its course it lies between the Tibialis anticus and Extensor longus digitorum; in the middle third, between the Tibialis anticus and Extensor proprius hallucis. At the bend of the ankle it is crossed by the tendon of the Extensor proprius hallucis, and lies between it and the innermost tendon of the Extensor longus digitorum. It is covered, in the upper two-thirds of its course, by the muscles which lie on either side of it and by the deep fascia; in the lower third, by the integument, anterior annular ligament, and fascia.

The anterior tibial artery is accompanied by two veins (vene comites), which lie one on each side of the artery; the anterior tibial nerve lies at first to its outer side, and about the middle of the leg is placed superficial to it; at the lower part of the artery the nerve is generally again on the outer side.

**Peculiarities in Size.**—This vessel may be diminished in size, may be deficient to a greater or less extent, or may be entirely wanting, its place being supplied by perforating branches from the posterior tibial or by the anterior division of the peroneal artery.

**Course.**—The artery occasionally deviates in its course toward the fibular side of the leg, regaining its usual position beneath the annular ligament at the front of the ankle. In two instances the vessel has been found to approach the surface in the middle of the leg, being covered merely by the integument and fascia below that point.

**Surface Marking.** —A line drawn from the inner side of the head of the fibula to midway between the two malleoli will mark the course of the artery, the point where the artery comes in front of the interosseous membrane being in this line, one and a quarter inches below the level of the head of the fibula.

**Surgical Anatomy.**—The anterior tibial artery may be tied in the upper or lower part of the leg. In the upper part the operation is attended with great difficulty, on account of the depth of the vessel from the surface. An incision about four inches in length should be made through the integument, midway between the spine of the tibia and the outer margin of the fibula, the fascia and intermuscular septum between the Tibialis anticus and Extensor longus digitorum being divided to the same extent. The foot must be flexed to relax these muscles, and they must be separated from each other by the finger. The artery is then exposed deeply seated, lying upon the interosseous membrane, the nerve lying externally, and one of the veins comites on either side; these must be separated from the artery before the aneurism needle is passed round it.

To tie the vessel in the lower third of the leg above the ankle-joint an incision about three inches in length should be made through the integument between the tendons of the Tibialis anticus and Extensor proprius hallucis muscles, the deep fascia being divided to the same extent. The tendon on either side should be held aside, when the vessel will be seen lying upon the tibia, with the nerve superficial to it and one of the veins comites on either side.

The branches of the anterior tibial artery are—

| Muscular. | Posterior Recurrent Tibial. |
| Internal Malleolar. | Superior Fibular. |
| External Malleolar. | Anterior Recurrent Tibial. |

The **posterior recurrent tibial** is not a constant branch, and is given off from the anterior tibial before that vessel passes through the interosseous space. It ascends beneath the Popliteus muscle, which it supplies, and anastomoses with the lower articular branches of the popliteal artery, giving off an offset to the superior tibio-fibular joint.

The **superior fibular** is sometimes given off from the anterior tibial, sometimes from the posterior tibial. It passes outward, round the neck of the fibula, through the Soleus, which it supplies, and ends in the substance of the Peroneus longus muscle.

The **anterior recurrent tibial branch** arises from the anterior tibial as soon as that vessel has passed through the interosseous space; it ascends in the Tibialis anticus muscle, and ramifies on the front and sides of the knee-joint, anastomosing with the articular branches of the popliteal and with the anastomotica magna.

The **muscular branches** are numerous: they are distributed to the muscles...
THE DORSALIS PEDIS ARTERY.

which lie on each side of the vessel, some piercing the deep fascia to supply the integument, others passing through the interosseous membrane, and anastomosing with branches of the posterior tibial and peroneal arteries.

The malleolar arteries supply the ankle-joint. The internal arises about two inches above the articulation, and passes beneath the tendons of the Extensor proprius hallucis and Tibialis anticus to the inner ankle, upon which it ramifies, anastomosing with branches of the posterior tibial and internal plantar arteries and with the internal calcanean from the posterior tibial. The external passes beneath the tendons of the Extensor longus digitorum and Peroneus tertius, and supplies the outer ankle, anastomosing with the anterior peroneal artery and with ascending branches from the tarsal branch of the dorsalis pedis.

The Dorsalis Pedis Artery (Fig. 378).

The dorsalis pedis, the continuation of the anterior tibial, passes forward from the bend of the ankle along the tibial side of the foot to the back part of the first intermetatarsal space, where it divides into two branches, the dorsalis hallucis, and communicating, or first dorsal interosseous artery and plantar digital respectively.

Relations.—This vessel, in its course forward, rests upon the astragalus, navicular, and internal cuneiform bones and the ligaments connecting them, being covered by the integument and fascia, anterior annular ligament, and crossed near its termination by the innermost tendon of the Extensor brevis digitorum. On its tibial side is the tendon of the Extensor proprius hallucis; on its fibular side, the innermost tendon of the Extensor longus digitorum, and the termination of the anterior tibial nerve. It is accompanied by two veins.

Peculiarities in Size.—The dorsal artery of the foot may be larger than usual, to compensate for a deficient plantar artery; or it may be deficient in its terminal branches to the toes, which are then derived from the internal plantar; or its place may be supplied altogether by a large anterior peroneal artery.

Position.—This artery frequently curves outward, lying external to the line between the middle of the ankle and the back part of the first interosseous space.

Surface Marking.—The dorsalis pedis artery is indicated on the surface of the dorsum of the foot by a line drawn from the centre of the space between the two malleoli to the back of the first intermetatarsal space.

Surgical Anatomy.—This artery may be tied, by making an incision through the integument between two and three inches in length, on the fibular side of the tendon of the Extensor proprius hallucis, in the interval between it and the inner border of the short Extensor muscle. The incision should not extend farther forward than the back part of the first intermetatarsal space, as the artery divides in that situation. The deep fascia being divided to the same extent, the artery will be exposed, the nerve lying upon its outer side.
Branches.—The branches of the dorsalis pedis are—the

<table>

</tr>
</thead>
<tbody>
<tr>
<td>Metatarsal—Interosseous.</td>
<td>Communicating.</td>
</tr>
</tbody>
</table>

The **tarsal artery** arises from the dorsalis pedis, as that vessel crosses the navicular bone; it passes in an arched direction outward, lying upon the tarsal bones, and covered by the Extensor brevis digitorum; it supplies that muscle and the articulations of the tarsus, and anastomoses with branches from the metatarsal, external malleolar, peroneal, and external plantar arteries.

The **metatarsal** arises a little anterior to the preceding; it passes outward to the outer part of the foot, over the bases of the metatarsal bones, beneath the tendons of the short Extensor, its direction being influenced by its point of origin; and it anastomoses with the tarsal and external plantar arteries. This vessel gives off three branches, the **interosseous arteries**, which pass forward upon the three outer Dorsal interossei muscles, and, in the clefts between the toes, divide into two dorsal collateral branches for the adjoining toes. At the back part of each interosseous space these vessels receive the posterior perforating branches from the plantar arch, and at the fore part of each interosseous space they are joined by the anterior perforating branches from the digital arteries. The outermost interosseous artery gives off a branch which supplies the outer side of the little toe.

The **dorsalis hallucis** (first dorsal interosseous) runs forward along the outer border of the first metatarsal bone, and at the cleft between the first and second toes divides into two branches, one of which passes inward, beneath the tendon of the Extensor proprius hallucis, and is distributed to the inner border of the great toe; the outer branch bifurcates, to supply the adjoining sides of the great and second toes.

The **communicating artery** or **Plantar digital** dips down into the sole of the foot, between the two heads of the First dorsal interosseous muscle, and inosculates with the termination of the external plantar artery to complete the plantar arch. It here gives off two digital branches: one runs along the inner side of the great toe on its plantar surface; the other passes forward along the first interosseous space, and bifurcates at the cleft for the supply of the adjacent sides of the great and second toes.

**The Posterior Tibial Artery.**

The **posterior tibial** is an artery of large size, which extends obliquely downward from the lower border of the Popliteus muscle, along the tibial side of the leg, to the fossa between the inner ankle and the heel, where it divides beneath the origin of the Abductor hallucis, on a level with a line drawn from the point of the internal malleolus to the centre of the convexity of the heel, into the **internal** and **external plantar arteries**. At its origin it lies opposite the interval between the tibia and fibula; as it descends, it approaches the inner side of the leg, lying behind the tibia, and, in the lower part of its course, is situated midway between the inner malleolus and the tuberosity of the os calcis.

**Relations.**—It lies successively upon the Tibialis posticus, the Flexor longus digitorum, the tibia, and the back part of the ankle-joint. It is **covered** by the deep transverse fascia, which separates it above from the Gastrocnemius and Soleus muscles. In the lower third, where it is more superficial, it is covered only by the integument and fascia, and runs parallel with the inner border of the tendo Achillis. It is accompanied by two veins, and by the posterior tibial nerve, which lies at first to the inner side of the artery, but soon crosses it, and is, in the greater part of its course, on its outer side.
THE POSTERIOR TIBIAL ARTERY.

Plan of the Relations of the Posterior Tibial Artery.

In front.
- Tibialis posticus.
- Flexor longus digitorum.
- Tibia.
- Ankle-joint.

Inner side.
- Posterior tibial nerve, upper third.

Behind.
- Integument and fascia.
- Gastrocnemius.
- Solens.
- Deep transverse fascia.
- Posterior tibial nerve.

Outer side.
- Posterior tibial nerve, lower two-thirds.

Behind the Inner ankle the tendons and blood-vessels are arranged in the following order, from within outward: First, the tendons of the Tibialis posticus and Flexor longus digitorum, lying in the same groove, behind the inner malleolus, the former being the most internal. External to these is the posterior tibial artery, having a vein on either side; and, still more externally, the posterior tibial nerve. About half an inch nearer the heel is the tendon of the Flexor longus hallucis.

Peculiarities in Size.—The posterior tibial is not unfrequently smaller than usual, or absent, its place being supplied by a large peroneal artery which passes inward at the lower end of the tibia and either joins the small tibial artery or continues alone to the sole of the foot.

Surface Marking.—The course of the posterior tibial artery is indicated by a line drawn from a point one inch below the centre of the popliteal space to midway between the tip of the internal malleolus and the centre of the convexity of the heel.

Surgical Anatomy.—The application of a ligature to the posterior tibial may be required in cases of wound of the sole of the foot attended with great haemorrhage, when the vessel should be tied at the inner ankle. In cases of wound of the posterior tibial it will be necessary to enlarge the opening so as to expose the vessel at the wounded point, excepting where the vessel is injured by a punctured wound from the front of the leg. In cases of aneurism from wound of the artery low down, the vessel should be tied in the middle of the leg. But in aneurism of the posterior tibial high up it would be better to tie the femoral artery.

To tie the posterior tibial artery at the ankle, a semilunar incision should be made through the integument, about two inches and a half in length, midway between the heel and inner ankle or a little nearer the latter. The subcutaneous cellular tissue having been divided, a strong and dense fascia, the internal annular ligament, is exposed. This ligament is continuous above with the deep fascia of the leg, covers the vessels and nerves, and is intimately adherent to the sheaths of the tendons. This having been cautiously divided upon a director, the sheath of the vessels is exposed, and, being opened, the artery is seen with one of the venae comites on each side. The aneurism needle should be passed round the vessel from the heel toward the ankle, in order to avoid the posterior tibial nerve, care being at the same time taken not to include the venæ comites.

The vessel may also be tied in the lower third of the leg by making an incision, about three inches in length, parallel with the inner margin of the tendo Achillis. The internal saphenous vein being carefully avoided, the two layers of fascia must be divided upon a director, when the artery is exposed along the outer margin of the Flexor longus digitorum, with one of its venæ comites on either side and the nerve lying external to it.

To tie the posterior tibial in the middle of the leg is a very difficult operation, on account of the great depth of the vessel from the surface. The patient being placed in the recumbent position, the injured limb should rest on its outer side, the knee being partially bent and the foot extended, so as to relax the muscles of the calf. An incision about four inches in length should then be made through the integument a finger's breadth behind the inner margin of the tibia, taking care to avoid the internal saphenous vein. The deep fascia having been divided, the margin of the Gastrocnemius is exposed, and must be drawn aside, and the tibial attachment of the Solens divided, a director being previously passed beneath it. The artery may now be felt pulsating beneath the deep fascia about an inch from the margin of the tibia. The fascia having been divided, and the limb placed in such a position as to relax the muscles of the calf as much as possible, the veins should be separated from the artery, and the aneurism needle passed round the vessel from without inward, so as to avoid wounding the posterior tibial nerve.
The branches of the posterior tibial artery are—

- **Peroneal.**
- **Muscular.**
- **Nutrient.**
- **Communicating.**

**Internal Calcanean.**

The **Peroneal Artery** lies, deeply seated, along the back part of the fibular side of the leg. It arises from the posterior tibial about an inch below the lower border of the Popliteus muscle, passes obliquely outward to the fibula, and then descends along the inner border of that bone to the lower third of the leg, where it gives off the **anterior peroneal.** It then passes as the **posterior peroneal,** across the articulation between the tibia and fibula to the outer side of the os calcis, where it gives off its terminal branches, the **external calcanean.**

**Relations.**—This vessel rests at first upon the Tibialis posticus, and then, for the greater part of its course, in a fibrous canal between the origins of the Flexor longus hallucis and Tibialis posticus, covered or surrounded by the fibres of the Flexor longus hallucis. It is **covered,** in the upper part of its course, by the Soleus and deep transverse fascia; **below,** by the Flexor longus hallucis.

**Plan of the Relations of the Peroneal Artery.**

*In front.*
- **Tibialis posticus.**
- Flexor longus hallucis.

*Outer side.*
- Fibula.
- Flexor longus hallucis.

*Peroneal Artery.*

*Inner side.*
- Flexor longus hallucis.

*Behind.*
- Soleus.
- Deep transverse fascia.
- Flexor longus hallucis.

**Peculiarities in Origin.**—The peroneal artery may arise three inches below the Popliteus, or from the posterior tibial high up, or even from the popliteal.

**Its size** is more frequently increased than diminished; and then it either reinforces the posterior tibial by its junction with it, or altogether takes the place of the posterior tibial in the lower part of the leg and foot, the latter vessel only existing as a short muscular branch. In those rare cases where the peroneal artery is smaller than usual a branch from the posterior tibial supplies its place, and a branch from the anterior tibial compensates for the diminished anterior peroneal artery. In one case the peroneal artery has been found entirely wanting.

The anterior peroneal is sometimes enlarged, and takes the place of the dorsal artery of the foot.

The branches of the peroneal are—

- **Muscular.**
- **Nutrient.**
- **Anterior Peroneal.**
- **Communicating.**
- **Posterior Peroneal.**
- **External Calcanean.**

**Muscular Branches.**—The **peroneal artery** in its course gives off branches to the Soleus, Tibialis posticus, Flexor longus hallucis, and Peronei muscles.

The **nutrient artery** supplies the fibula.

The **Anterior peroneal** pierces the interosseous membrane, about two inches above the outer malleolus, to reach the front part of the leg, and, passing down beneath the Peroneus tertius to the outer ankle, ramifies on the front and outer side of the tarsus, anastomosing with the external malleolar and tarsal arteries.

The **communicating** is given off from the peroneal about an inch from its lower end, and, passing inward, joins the communicating branch of the posterior tibial.

The **Posterior peroneal** passes down behind the outer ankle to the back of the external malleolus, to terminate in branches which ramify on the outer surface and back of the os calcis.
The *external calcanean* are the terminal branches of the peroneal artery; they pass to the outer side of the heel, and communicate with the *external malleolar*, and, on the back of the heel, with the *internal calcanean* arteries.

The *nutrient artery* of the tibia arises from the posterior tibial near its origin, and, after supplying a few muscular branches, enters the nutrient canal of that bone, which it traverses obliquely from above downward. This is the largest nutrient artery of bone in the body.

The *muscular branches* of the posterior tibial are distributed to the Soleus and deep muscles along the back of the leg.

The *communicating branch*, to join a similar branch of the peroneal, runs transversely across the back of the tibia, about two inches above its lower end, passing beneath the Flexor longus hallucis.

The *internal calcanean* are several large arteries which arise from the posterior tibial just before its division; they are distributed to the fat and integument behind the tendo Achillis and about the heel, and to the muscles on the inner side of the sole, anastomosing with the peroneal and internal malleolar, and, on the back of the heel, with the external calcanean arteries.

The *internal plantar artery* (Figs. 379, 380), much smaller than the external, passes forward along the inner side of the foot. It is at first situated above the Abductor hallucis, and then between it and the Flexor brevis digitorum, both of which it supplies. At the base of the first metatarsal bone, where it has become much diminished in size, it passes along the inner border of the great toe, inosculating with its digital branch.

The *external plantar artery*, much larger than the internal, passes obliquely outward and forward to the base of the fifth metatarsal bone. It then turns obliquely inward to the interval between the bases of the first and second metatarsal bones, where it anastomoses with the plantar digital branch from the dorsalis pedis artery, thus completing the *plantar arch*. As this artery passes

---

1 This refers to the erect position of the body. In the ordinary position for dissection the artery is deeper than the muscle.
outward, it is first placed between the os calcis and Abductor hallucis, and then between the Flexor brevis digitorum and Flexor accessorius, and as it passes forward to the base of the little toe, it lies more superficially between the Flexor brevis digitorum and Abductor minimi digiti, covered by the deep fascia and integument. The remaining portion of the vessel is deeply situated: it extends from the base of the metatarsal bone of the little toe to the back part of the first interosseous space, and forms the plantar arch; it is convex forward, lies upon the Interossei muscles opposite the tarsal ends of the metatarsal bones, and is covered by the Adductor obliquus hallucis, the flexor tendons of the toes, and the Lumbricales.

**Surface Marking.**—The course of the internal plantar artery is represented by a line drawn from the mid-point between the tip of the internal malleolus and the centre of the convexity of the heel to the middle of the under surface of the great toe; the external plantar by a line from the same point to within a finger's breadth of the tuberosity of the fifth metatarsal bone. The plantar arch is indicated by a line drawn from this point; i.e. a finger's breadth internal to the tuberosity of the fifth metatarsal bone transversely across the foot to the back of the first interosseous space.

**Surgical Anatomy.**—Wounds of the plantar arch are always serious, on account of the depth of the vessel and the important structures which must be interfered with in an attempt to ligature it. Delorme has shown that it may be ligatured from the dorsum of the foot in almost any part of its course by removing a portion of one of the three middle metatarsal bones.

**Branches.**—The plantar arch, besides distributing numerous branches to the muscles, integument, and fascia in the sole, gives off the following branches:

1. **Posterior Perforating.**
2. **Digital—Anterior Perforating.**

The **Posterior Perforating** are three small branches which ascend through the back part of the three outer interosseous spaces, between the heads of the Dorsal interossei muscles, and anastomose with the interosseous branches from the metatarsal artery.

The **Digital Branches** are four in number, and supply the three outer toes and half the second toe. The *first* passes outward from the outer side of the plantar arch, and is distributed to the outer side of the little toe, passing in its course beneath the Abductor and short Flexor muscles. The *second, third, and fourth* run forward along the interosseous spaces, and on arriving at the clefts between the toes divide into collateral branches, which supply the adjacent sides of the three outer toes and the outer side of the second. At the bifurcation of the toes each digital artery sends upward, through the fore part of the corresponding interosseous space, a small branch, which inosulates with the interosseous branches of the metatarsal artery. These are the **anterior perforating branches**.

From the arrangement already described of the distribution of the vessels to the toes it will be seen that both sides of the three outer toes and the outer side of the second toe are supplied by branches from the plantar arch; both sides of the great toe and the inner side of the second are supplied by the plantar digital branch of the dorsalis pedis.
THE VEINS.

The Veins are the vessels which serve to return the blood from the capillaries of the different parts of the body to the heart. They consist of two distinct sets of vessels, the pulmonary and systemic.

The Pulmonary Veins are concerned in the circulation in the lungs. Unlike other vessels of this kind, they contain arterial blood, which they return from the lungs to the left auricle of the heart.

The Systemic Veins are concerned in the general circulation; they return the venous blood from the body generally to the right auricle of the heart.

The Portal Vein, an appendage to the systemic venous system, is confined to the abdominal cavity, returning the venous blood from the viscera of digestion, and carrying it to the liver by a single trunk of large size, the vena portae. This vessel ramifies in the substance of the liver and breaks up into a minute network of capillaries. These capillaries then re-collect to form the hepatic veins, by which the blood is conveyed to the inferior vena cava.

The veins, like the arteries, are found in nearly every tissue of the body. They commence by minute plexuses which receive the blood from the capillaries. The branches which have their commencement in these plexuses unite together into trunks, and these, in their passage toward the heart, constantly increase in size as they receive tributaries or join other veins. The veins are larger and altogether more numerous than the arteries; hence the entire capacity of the venous system is much greater than that of the arterial, the pulmonary veins excepted, which do not exceed in capacity the pulmonary arteries. From the combined area of the smaller venous branches being greater than the main trunks, it results that the venous system represents a cone, the summit of which corresponds to the heart, its base to the circumference of the body. In form the veins are not perfectly cylindrical like the arteries, their walls being collapsed when empty, and the uniformity of their surface being interrupted at intervals by slight constrictions, which indicate the existence of valves in their interior. They usually retain, however, the same calibre as long as they receive no branches.

The veins communicate very freely with one another, especially in certain regions of the body, and this communication exists between the larger trunks as well as between the smaller branches. Thus, in the cavity of the cranium and between the veins of the neck, where obstruction would be attended with imminent danger to the cerebral venous system, we find that the sinuses and larger veins have large and very frequent anastomoses. The same free communication exists between the veins throughout the whole extent of the spinal canal, and between the veins composing the various venous plexuses in the abdomen and pelvis, as the spermatic, uterine, vesical, and prostatic.

The systemic veins are subdivided into three sets: superficial, deep, and sinuses.

The Superficial or Cutaneous Veins are found between the layers of the superficial fascia, immediately beneath the integument; they return the blood from these structures, and communicate with the deep veins by perforating the deep fascia.

The Deep Veins accompany the arteries, and are usually enclosed in the same sheath with these vessels. With the smaller arteries—as the radial, ulnar, brachial, tibial, peroneal—they exist generally in pairs, one lying on each side of the vessel, and are called nerves comites. The larger arteries—as the axillary, subclavian, popliteal, and femoral—have usually only one accompanying vein. In certain
organs of the body, however, the deep veins do not accompany the arteries; for instance, the veins in the skull and spinal canal, the hepatic veins in the liver, and the larger veins returning blood from the osseous tissue.

Sinuses are venous channels which, in their structure and mode of distribution, differ altogether from the veins. They are found only in the interior of the skull, and are formed by a separation of the layers of the dura mater, their outer coat consisting of fibrous tissue, their inner of an endothelial layer continuous with the lining membrane of the veins.

Veins have thinner walls than arteries, the difference in thickness being due to the small amount of elastic and muscular tissues which the veins contain. The superficial veins usually have thicker coats than the deep veins, and the veins of the lower limb are thicker than those of the upper.

The minute structure of these vessels has been described in the section on General Anatomy.

THE PULMONARY VEINS.

The Pulmonary Veins return the arterial blood from the lungs to the left auricle of the heart. They are four in number, two for each lung. The pulmonary differ from other veins in several respects: 1. They carry arterial instead of venous blood. 2. They are destitute of valves. 3. They are only slightly larger than the arteries they accompany. 4. They accompany those vessels singly. They commence in a capillary network upon the walls of the air-cells, where they are continuous with the ramifications of the pulmonary artery, and, uniting together, form a single trunk for each lobe. These branches, uniting successively, form a single trunk for each lobe, three for the right and two for the left lung. The vein from the middle lobe of the right lung unites with that from the upper lobe, in most cases, forming two trunks on each side, which open separately into the left auricle. Occasionally they remain separate; there are then three veins on the right side. Not unfrequently the two left pulmonary veins terminate by a common opening.

Within the lung, the branches of the pulmonary artery are in front, the veins behind, and the bronchi between the two.

At the root of the lung, the veins are in front, the artery in the middle, and the bronchus behind.

Within the pericardium, their anterior surface is invested by the serous layer of this membrane. The right pulmonary veins pass behind the right auricle and ascending aorta; the left pass in front of the thoracic aorta with the left pulmonary artery.

THE SYSTEMIC VEINS.

The systemic veins may be arranged into three groups: 1. Those of the head and neck, upper extremity, and thorax, which terminate in the superior vena cava. 2. Those of the lower limb, pelvis, and abdomen, which terminate in the inferior vena cava. 3. The cardiac veins, which open directly into the right auricle of the heart.

VEINS OF THE HEAD AND NECK.

The veins of the head and neck may be subdivided into three groups: 1. The veins of the exterior of the head and face. 2. The veins of the neck. 3. The veins of the diploë and interior of the cranium.

Veins of the Exterior of the Head.

The veins of the exterior of the head and face are—the

Frontal.  Temporal.
Supra-orbital.  Internal Maxillary.
Angular.  Temporo-maxillary.
Facial.  Posterior Auricular.
Occipital.
The **frontal vein** commences on the anterior part of the skull by a venous plexus which communicates with the anterior tributaries of the temporal vein. The veins converge to form a single trunk, which runs downward near the middle line of the forehead parallel with the vein of the opposite side, and unites with it at the root of the nose by a transverse branch called the *nasal arch*. Occasionally the frontal veins join to form a single trunk, which bifurcates at the root of the nose into the two angular veins. At the root of the nose the veins diverge and join the *supra-orbital vein*, at the inner angle of the orbit, to form the *angular vein*.

The **supra-orbital vein** commences on the forehead, communicating with the anterior temporal vein, and runs downward and inward, superficial to the Occipito-frontalis muscle, receiving tributaries from the neighboring structures, and joins the frontal vein at the inner angle of the orbit to form the *angular vein*.

The **angular vein**, formed by the junction of the frontal and supra-orbital veins, runs obliquely downward and outward on the side of the root of the nose, and receives the veins of the ala nasi on its inner side and the superior palpebral veins on its outer side; it moreover communicates with the ophthalmic vein, thus
establishing an important anastomosis between this vessel and the cavernous sinus. Some small veins from the dorsum of the nose terminate in the nasal arch.

The **facial vein** commences at the side of the root of the nose, being a direct continuation of the angular vein. It passes obliquely downward and outward beneath the Zygomaticus major and minor muscles, descends along the anterior border of the Masseter, crosses over the body of the lower jaw with the facial artery, and, passing obliquely outward and backward beneath the Platysma and cervical fascia, unites with a branch of communication from the temporo-maxillary vein to form a trunk of large size which enters the internal jugular. From near its termination a *communicating* branch often runs down the anterior border of the Sterno-mastoid to join the lower part of the anterior jugular.

**Tributaries.**—The facial vein receives, near the angle of the mouth, communicating tributaries of considerable size (the *deep facial* or *anterior internal maxillary vein*) from the pterygoid plexus. It is also joined by the inferior palpebral, the superior and inferior labial veins, the buccal veins from the cheek, and the masseteric veins. Below the jaw it receives the submental; the inferior palatine, which returns the blood from the plexus around the tonsil and soft palate; the submaxillary vein, which commences in the submaxillary gland; and, generally, the ranine vein.

**Surgical Anatomy.**—There are some points about the facial vein which render it of great importance in surgery. It is not so flaccid as are most superficial veins, and, in consequence of this, remains more patent when divided. It has, moreover, no valves. It communicates freely with the intracranial circulation, not only at its commencement by its tributaries, the angular and supra-orbital veins, communicating with the ophthalmic vein, a tributary of the cavernous sinus, but also by its deep branch, which communicates through the pterygoid plexus with the cavernous sinus by branches which pass through the foramen ovale and foramen lacerum medium (see page 661). These facts have an important bearing upon the surgery of some diseases of the face, for on account of its patency the facial vein favors septic absorption, and therefore any phlegmonous inflammation of the face following a poisoned wound is liable to set up thrombosis in the facial vein. And on account of its communications with the cerebral sinuses these thrombi are apt to extend upward into them, and detached portions may give rise to purulent foci in other parts of the body, and so induce a fatal issue.

The **Temporal Vein** commences by a minute plexus on the side and vertex of the skull, which communicates with the frontal and supra-orbital veins in front, the corresponding vein of the opposite side, and the posterior auricular and occipital veins behind. From this network anterior and posterior branches are formed which unite above the zygoma, forming the trunk of the vein. This trunk is joined in this situation by a large vein, the *middle temporal*, which receives the blood from the substance of the Temporal muscle and pierces the fascia at the upper border of the zygoma. The temporal vein then descends between the external auditory meatus and the condyle of the jaw, enters the substance of the parotid gland, and unites with the internal maxillary vein to form the temporo-maxillary vein.

**Tributaries.**—The temporal vein receives in its course some parotid veins, an articular branch from the articulation of the jaw, anterior auricular veins from the external ear, and a vein of large size, the *transverse facial*, from the side of the face. The middle temporal vein, previous to its junction with the temporal vein, receives a branch, the *orbital vein*, which is formed by some external palpebral branches, and passes backward between the layers of the temporal fascia.

The **Internal Maxillary Vein** is a vessel of considerable size, receiving branches which correspond with those of the internal maxillary artery. Thus it receives the middle meningeal veins, the deep temporal, the pterygoid, masseteric, buccal, alveolar, some palatine veins, and the inferior dental. These branches form a large plexus, the *pterygoid*, which is placed between the Temporal and External pterygoid and partly between the Pterygoid muscles. This plexus communicates very freely with the facial vein and with the cavernous sinus by branches through the foramen Vesalii at the base of the skull. The trunk of the vein then passes
backward behind the neck of the lower jaw, and unites with the temporal vein, forming the temporo-maxillary vein.

The Temporo-Maxillary Vein, formed by the union of the temporal and internal maxillary veins, descends in the substance of the parotid gland on the outer surface of the external carotid artery, between the ramus of the jaw and the Sterno-mastoid muscle, and divides into two branches, one of which passes inward to join the facial vein; the other is joined by the posterior auricular vein and becomes the external jugular.

The Posterior Auricular Vein commences upon the side of the head by a plexus which communicates with the tributaries of the temporal and occipital veins. The vein descends behind the external ear and joins the temporo-maxillary vein, forming the external jugular. This vessel receives the stylo-mastoid vein and some tributaries from the back part of the external ear.

The Occipital Veins commence at the back part of the vertex of the skull by a plexus in a similar manner to the other veins. These unite and form one or two veins, which follow the course of the occipital artery, passing deeply beneath the muscles of the back part of the neck, and terminate in the internal jugular, occasionally in the external jugular vein. As these veins pass across the mastoid portion of the temporal bone, one of them receives the mastoid vein, which thus establishes a communication with the lateral sinus.

The Veins of the Neck.

The veins of the neck, which return the blood from the head and face, are—the

<table>

<td>Vertebral.</td>
<td></td>
</tr>
</tbody>
</table>

The External Jugular Vein receives the greater part of the blood from the exterior of the cranium and deep parts of the face, being formed by the junction of the posterior division of the temporo-maxillary and posterior auricular veins. It commences in the substance of the parotid gland, on a level with the angle of the lower jaw, and runs perpendicularly down the neck in the direction of a line drawn from the angle of the jaw to the middle of the clavicle. In its course it crosses the Sterno-mastoid muscle, and runs parallel with its posterior border as far as its attachment to the clavicle, where it perforates the deep fascia, and terminates in the subclavian vein, on the outer side of or in front of the Scalennus anticus muscle. In the neck it is separated from the Sterno-mastoid by the anterior layer of the deep cervical fascia, and is covered by the Platysma, the superficial fascia, and the integument. This vein is crossed about its middle by the superficial collateral nerve, and its upper half is accompanied by the auricularis magnus nerve. The external jugular vein varies in size, bearing an inverse proportion to that of the other veins of the neck; it is occasionally double. It is provided with two pairs of valves, the lower pair being placed at its entrance into the subclavian vein, the upper pair in most cases about an inch and a half above the clavicle. The portion of vein between the two sets of valves is often dilated, and is termed the sinus. These valves do not prevent the regurgitation of the blood or the passage of injection from below upward.1

Surgical Anatomy.—Venesection used formerly to be performed on the external jugular vein, but is now probably never resorted to. The anatomical point to be remembered in performing this operation is to cut across the fibres of the Platysma myoides in opening the vein, so that by their contraction they will expose the orifice in the vein and so allow the flow of blood.

Tributaries.—This vein receives the occipital occasionally, the posterior external jugular, and near its termination, the suprascapular and transverse cervical veins.

1 The student may refer to an interesting paper by Dr. Struthers, "On Jugular Venesection in Asphyxia, anatomically and experimentally considered, including the Demonstration of Valves in the Veins of the Neck," in the Edinburgh Medical Journal for November, 1856.
THE VEINS

It communicates with the anterior jugular, and, in the substance of the parotid, receives a large branch of communication from the internal jugular.

The Posterior External Jugular Vein commences in the occipital region, and returns the blood from the integument and superficial muscles in the upper and back part of the neck, lying between the Splenius and Trapezius muscles. It runs down the back part of the neck, and opens into the external jugular just below the middle of its course.

The Anterior Jugular Vein commences near the hyoid bone from the convergence of several superficial veins from the submaxillary region. It passes down between the median line and the anterior border of the Sterno-mastoid, and at the lower part of the neck passes beneath that muscle to open into the termination of the external jugular or into the subclavian vein (Fig. 388). This vein varies considerably in size, bearing almost always an inverse proportion to the external jugular. Most frequently there are two anterior jugulars, a right and left, but occasionally only one. This vein receives some laryngeal veins, and occasionally a small thyroid vein. Just above the sternum the two anterior jugular veins communicate by a transverse trunk, which receives tributaries from the inferior thyroid veins. It also communicates with the internal jugular. There are no valves in this vein.

The Internal Jugular Vein collects the blood from the interior of the cranium, from the superficial parts of the face, and from the neck. It commences just external to the jugular foramen, at the base of the skull, being formed by the coalescence of the lateral and inferior petrosal sinuses (Fig. 386). At its origin it is somewhat dilated, and this dilatation is called the sinus, or gulf, of the internal jugular vein. It runs down the side of the neck in a vertical direction, lying at first on the outer side of the internal carotid, and then on the outer side of the common carotid, and at the root of the neck unites with the subclavian vein to form the innominate vein. The internal jugular vein, at its commencement, lies upon the Rectus capitis lateralis, and behind the internal carotid and the nerves passing through the jugular foramen; lower down, the vein and artery lie upon the same plane, the glosso-pharyngeal and hypoglossal nerves passing forward between them; the pneumogastric descends between and behind them in the same sheath, and the spinal accessory passes obliquely outward behind the vein. At the root of the neck the vein of the right side is placed at a little distance from the artery; on the left side it usually lies over the artery at its lower part. The right internal jugular vein crosses the first part of the subclavian artery. The vein is of considerable size, but varies in different individuals, the left one being usually the smaller. It is provided with a pair of valves, which are placed at its point of termination or from half to three-quarters of an inch above it.

Tributaries.—This vein receives in its course the facial, lingual, pharyngeal, superior and middle thyroid veins, and sometimes the occipital. At its point of junction with the branch common to the temporo-maxillary and facial veins it becomes greatly increased in size.

The lingual veins commence on the dorsum, sides, and under surface of the tongue, and, passing backward, following the course of the lingual artery and its branches, terminate in the internal jugular. Sometimes the ranine vein, which is a branch of considerable size commencing below the tip of the tongue, joins the lingual. Generally, however, it passes backward, crosses the Hyo-glossus muscle in company with the hypoglossal nerve, and joins the facial.

The pharyngeal vein commences in a minute plexus, the pharyngeal, at the back part and sides of the pharynx, and, after receiving meningeal tributaries and the Vidian and spheno-palatine veins, terminates in the internal jugular. It occasionally opens into the facial, lingual, or superior thyroid vein.

The superior thyroid vein commences in the substance and on the surface of the thyroid gland by tributaries corresponding with the branches of the superior thyroid artery, and terminates in the upper part of the internal jugular vein.
The middle thyroid vein collects the blood from the lower part of the lateral lobe of the thyroid gland, and, being joined by some veins from the larynx and trachea, terminates in the lower part of the internal jugular vein.

The facial and occipital veins have been described above.

Surgical Anatomy.—The internal jugular vein occasionally requires ligature in cases of septic thrombosis of the lateral sinus from suppuration in the middle ear, in order to prevent embolism of the thoracic viscera. This operation has been performed recently in several cases with the most satisfactory results. The cases are generally those of chronic disease of the middle ear, with discharge of pus which perhaps has existed for many years. The patient is seized with acute septic inflammation, spreading to the mastoid cells, and consequent on this septic thrombosis of the lateral sinus extending to the internal jugular vein. Such cases are always extremely grave, for there is a danger of a portion of the septic clot being detached and causing septic embolism in the thoracic viscera. This may be mechanically prevented by ligature of the internal jugular vein in the middle of the neck. The operation is a comparatively simple one, and may be performed by an incision similar to that employed in ligature of the common carotid artery.

The Vertebral Vein commences in the occipital region by numerous small tributaries from the deep muscles at the upper and back part of the neck; these pass outward and enter the foramen in the transverse process of the atlas, and descend, forming a dense plexus around the vertebral artery in the canal formed by the transverse processes of the cervical vertebrae. This plexus unites at the lower part of the neck into two main trunks, one of which emerges from the foramen in the transverse process of the sixth cervical vertebra, and the other through that of the seventh, and, uniting, form a single vessel, which terminates at the root of the neck in the back part of the innominate vein near its origin, its mouth being guarded by a pair of valves. On the right side it crosses the first part of the subclavian artery.

Tributaries.—The vertebral vein receives in its course a vein from the inside of the skull through the posterior condylid foramen; muscular veins from the muscles in the prevertebral region; dorsi-spinal veins, from the back part of the cervical portion of the spine; meningo-rachidian veins, from the interior of the spinal canal; the anterior and posterior vertebral veins; and close to its termination it is joined by a small vein from the first intercostal space which accompanies the superior intercostal artery. (See page 666.)

The anterior vertebral vein commences in a plexus around the transverse processes of the upper cervical vertebrae, descends in company with the ascending cervical artery between the Scalenus anticus and Rectus capitis anticus major muscles, and opens into the vertebral vein just before its termination.

The posterior vertebral vein (the deep cervical) accompanies the profunda cervicis artery, lying between the Complexus and Semispinalis coli. It commences in the suboccipital region by communicating branches from the occipital vein and tributaries from the deep muscles at the back of the neck. It receives tributaries from the plexuses around the spinous processes of the cervical vertebrae, and terminates in the lower end of the vertebral vein.

The Veins of the Diploë.

The diploë of the cranial bones is channelled in the adult by a number of tortuous canals, which are lined by a more or less complete layer of compact tissue.

The veins they contain are large and capacious, their walls being thin, and formed only of endothelium resting upon a layer of elastic tissue, and they present at irregular intervals pouch-like dilatations, or culs-de-sac, which serve as reservoirs for the blood. These are the veins of the diploë; they can only be displayed by removing the outer table of the skull.

In adult life, as long as the cranial bones are distinct and separable, these veins are confined to the particular bones; but in old age, when the sutures are united, they communicate with each other and increase in size. These vessels communicate, in the interior of the cranium, with the meningeal veins and with
the sinuses of the dura mater, and on the exterior of the skull with the veins of the pericranium. They are divided into the frontal, which opens into the supra-orbital vein by an aperture in the supra-orbital notch; the anterior temporal, which is confined chiefly to the frontal bone, and opens into one of the deep temporal veins, after escaping by an aperture in the great wing of the sphenoid;

the posterior temporal, which is confined to the parietal bone, and terminates in the lateral sinus by an aperture at the posterior inferior angle of the parietal bone; and the occipital, the largest of the four, which is confined to the occipital bone, and opens either into the occipital vein or internally into the lateral sinus or torcular Herophili.

The Cerebral Veins.

The Cerebral Veins are remarkable for the extreme thinness of their coats in consequence of the muscular tissue in them being wanting, and for the absence of valves. They may be divided into two sets: the superficial, which are placed on the surface, and the deep veins, which occupy the interior of the organ.

The Superficial Cerebral Veins ramify upon the surface of the brain, being lodged in the sulci between the convolutions, a few running across the convolutions. They receive branches from the substance of the brain and terminate in the sinuses. They are named, from the position they occupy, superior, median, and inferior cerebral veins.

The Superior Cerebral Veins, eight to twelve in number on each side, return the blood from the convolutions on the superior surface of the hemisphere; they pass forward and inward toward the great longitudinal fissure, where they receive the median cerebral veins; near their termination they become invested with a tubular sheath of the arachnoid membrane, and open into the superior longitudinal sinus in the opposite direction to the course of the blood.

The Median Cerebral Veins return the blood from the convolutions of the mesial surface of the corresponding hemisphere; they open into the superior cerebral veins, or occasionally into the inferior longitudinal sinus.

The Inferior Cerebral Veins ramify on the lower part of the outer and on the under surface of the cerebral hemisphere. Some, collecting tributaries from the under surface of the anterior lobes of the brain, terminate in the cavernous sinus. One vein of large size, the middle cerebral vein, commences on the under surface
of the temporo-sphenoidal lobe, and, running along the fissure of Sylvius, opens into the cavernous sinus. Another large vein, the great anastomotic vein of Trolard, commences on the parietal lobe, runs along the horizontal limb of the fissure of Sylvius, and opens into the anterior part of the cavernous sinus under the lesser wing of the sphenoid. Others commence on the under surface of the base of the brain, and unite to form from three to five veins, which open into the superior petrosal and lateral sinuses from before backward.

The Deep Cerebral, or Ventricular Veins (vena Galeni), are two in number. They are formed by the union of two veins, the vena corporis striati, and the choroid vein, on either side. They run backward, parallel with one another, between the layers of the velum interpositum, and pass out of the brain at the great transverse fissure, between the posterior extremity, or splenium, of the corpus callosum and the tubercula quadrigemina, to enter the straight sinus. The two veins usually unite to form one before opening into the straight sinus.

The vena corporis striati commences in the groove between the corpus striatum and thalamus opticus, receives numerous veins from both of these parts, and unites behind the anterior pillar of the fornix with the choroid vein to form one of the vena Galeni.

The choroid vein runs along the whole length of the outer border of the choroid plexus, receiving veins from the hippocampus major, the fornix and corpus callosum, and unites, at the anterior extremity of the choroid plexus, with the vein of the corpus striatum.

The Cerebellar Veins occupy the surface of the cerebellum, and are disposed in three sets, superior, inferior, and lateral. The superior pass forward and inward across the superior vermiform process, and terminate in the straight sinus; some open into the vena Galeni. The inferior cerebellar veins, of large size, run transversely outward, and terminate by two or three trunks in the lateral sinuses. The lateral cerebellar veins terminate in the superior petrosal sinuses.

The perivasculary lymph-sheaths alluded to above (see page 87) are especially found in connection with the vessels of the brain. These vessels are enclosed in a sheath which acts as a lymphatic channel, through which the lymph is carried to the subarachnoid and subdural spaces, from which it is returned into the general circulation.

The Sinuses of the Dura Mater.

The sinuses of the dura mater are venous channels, analogous to the veins, their outer coat being formed by the dura mater; their inner, by a continuation of the lining membrane of the veins. They are fifteen in number, and are divided into two sets: 1, those situated at the upper and back part of the skull; 2, those at the base of the skull. The former are—

Superior Longitudinal. Straight Sinus.
Inferior Longitudinal. Lateral Sinuses.
Occipital Sinus.

The Superior Longitudinal Sinus occupies the attached margin of the falx cerebri. Commencing at the foramen cecum, through which it constantly communicates by a small branch with the veins of the nasal fossa, it runs from before backward, grooving the inner surface of the frontal, the adjacent margins of the two parietal, and the superior division of the crucial ridge of the occipital bone, and terminates by opening into the torcular Herophili. The sinus is triangular in form, narrow in front, and gradually increasing in size as it passes backward. On examining its inner surface it presents the internal openings of the superior cerebral veins, which run, for the most part, from behind forward, and open chiefly at the back part of the sinus, their orifices being concealed by fibrous folds; numerous fibrous bands (chordae Willsii) are also seen, extending transversely across the inferior angle of the sinus; and, lastly, some small, white, projecting bodies, the glandulae Pacchioni. This sinus receives the superior cerebral veins, numerous veins from the diploë and dura mater, and, at the posterior extremity
of the sagittal suture, veins from the pericranium, which pass through the parietal foramen.

The **torcular Herophili** is the dilated extremity of the superior longitudinal sinus. It is of irregular form, and is lodged on one side (generally the right) of the internal occipital protuberance. From it the lateral sinus of the side to which it is deflected is derived. It receives also the blood from the occipital sinus.

The **Inferior Longitudinal Sinus**, more correctly described as the *inferior longitudinal vein*, is contained in the posterior part of the free margin of the falx cerebri. It is of a cylindrical form, increases in size as it passes backward, and terminates in the straight sinus. It receives several veins from the falx cerebri, and occasionally a few from the mesial surface of the hemispheres.

The **Straight Sinus** is situated at the line of junction of the falx cerebri with the tentorium. It is triangular in form, increases in size as it proceeds backward, and runs obliquely downward and backward from the termination of the inferior longitudinal sinus to the lateral sinus of the opposite side to that into which the superior longitudinal sinus is prolonged. It communicates by a cross branch with the torcular Herophili. Beside the inferior longitudinal sinus, it receives the *venae Galeni* and the superior cerebellar veins. A few transverse bands cross its interior.

The **Lateral Sinuses** are of large size, and are situated in the attached margin of the tentorium cerebelli. They commence at the internal occipital protuberance, the one, generally the right, being the direct continuation of the superior longitudinal sinus, the other of the straight sinus. They pass horizontally outward to the base of the petrous portion of the temporal bone, then curve downward and inward on each side to reach the jugular foramen, where they terminate in the internal jugular vein. Each sinus rests, in its course, upon the inner surface of the occipital, the posterior inferior angle of the parietal, the mastoid portion of the temporal, and on the occipital, again just before its termination. These sinuses are frequently of unequal size, that formed by the superior longitudinal sinus being the larger, and they increase in size as they proceed from behind forward. The horizontal portion is of a triangular form, the curved portion semicylindrical. Their inner surface is smooth, and not crossed by the fibrous bands found in the other sinuses. These sinuses receive the blood from the superior petrosal sinuses at the base of the petrous portion of the temporal bone, and they unite with the inferior petrosal sinus, just external to the jugular foramen, to form the internal

![Fig. 388.—Vertical section of the skull, showing the sinuses of the dura mater.](image)
jugular vein (Fig. 386). They communicate with the veins of the perieranium by means of the mastoid and posterior condylloid veins, and they receive some of the inferior cerebral and inferior cerebellar veins and some veins from the diploë.

The Occipital is the smallest of the cranial sinuses. It is generally single, but occasionally there are two. It is situated in the attached margin of the falx cerebelli. It commences by several small veins around the margin of the foramen magnum, one of which joins the termination of the lateral sinus; it communicates with the posterior spinal veins and terminates in the torcular Herophili.

The sinuses at the base of the skull are—the

The Cavernous Sinuses are named from their presenting a reticulated structure. They are two in number, of large size, and placed one on each side of the sella turcica, extending from the sphenoidal fissure to the apex of the petrous portion of the temporal bone; they receive anteriorly the ophthalmic vein through the sphenoidal fissure, and open behind into the petrosal sinuses. On the inner wall of each sinus is found the internal carotid artery, accompanied by filaments of the carotid plexus and by the sixth nerve; and on its outer wall, the third, fourth, and ophthalmic division of the fifth nerve. These parts are separated from the blood flowing along the sinus by the lining membrane, which is continuous with the inner coat of the veins. The cavity of the sinus, which is larger behind than in front, is intersected by filaments of fibrous tissue and small vessels. The cavernous sinuses receive some of the cerebral veins; they communicate with the lateral sinuses by means of the superior and inferior petrosal, and with the facial vein through the ophthalmic. They also communicate with each other by means of the circular sinus.

Surgical Anatomy.—An arterio-venous communication may be established between the cavernous sinus and the carotid artery, as it lies in it, giving rise to a pulsating tumor in the orbit. These communications may be the result of injury, such as a bullet wound, a stab, or a blow or fall sufficiently severe to cause a fracture of the base of the skull in this situation, or they may occur idiopathically from the rupture of an aneurism or a diseased condition of the internal carotid artery. The disease begins with sudden noise and pain in the head, followed by exophthalmos, and development of a pulsating tumor at the margin of the orbit, with thrill and the characteristic bruit. In some cases the opposite orbit becomes affected by the passage of the arterial blood into the opposite sinus by means of the circular sinus. Or the arterial blood may find its way through the emissary veins (see page 663) into the petrogyoid plexus, and thence into the veins of the face. Pulsating tumors of the orbit may also be due to traumatic aneurism of one of the orbital arteries, and symptoms resembling those of pulsating tumor may be produced by pressure on the ophthalmic vein, as it enters the sinus, by an aneurism of the internal carotid artery.

The ophthalmic is a large vein which connects the angular vein at the inner angle of the orbit with the cavernous sinus; it pursues the same course as the ophthalmic artery, and receives tributaries corresponding to the branches derived from that vessel. Forming a short single trunk, it passes through
the inner extremity of the sphenoidal fissure and terminates in the cavernous sinus.

The Inferior Ophthalmic Vein.—Sometimes the veins from the floor of the orbit collect into a separate trunk, the *inferior ophthalmic vein*, which either passes out of the orbit through the spheno-maxillary fissure to join the pterygoid plexus of veins, or else, passing backward through the sphenoidal fissure, it enters the cavernous sinus, either by a separate opening or in common with the ophthalmic vein.

The Circular Sinus is formed by two transverse vessels which connect together the two cavernous sinuses, the one passing in front and the other behind the pituitary body, and thus forming with the cavernous sinuses a venous circle around the body. The anterior one is usually the larger of the two, and one or other is occasionally found to be absent.

The Superior Petrosal Sinus is situated along the superior border of the petrous portion of the temporal bone, in the front part of the attached margin of the tentorium. It is small and narrow, and connects together the cavernous and lateral sinuses at each side. It receives a cerebellar vein (*anterior lateral cerebellar*) from the anterior border of the cerebellum, and a vein from the internal ear.

The Inferior Petrosal Sinus is situated in the groove formed by the junction of the posterior border of the petrous portion of the temporal with the basilar process of the occipital. It commences in front at the termination of the cavernous sinus, and behind joins the lateral sinus after it has passed through the jugular foramen, the junction of these two sinuses forming the commencement of the internal jugular vein.

The junction of the two sinuses takes place at the lower border of, or just external to, the jugular foramen. The exact relation of the parts to one another in the foramen is as follows: The inferior petrosal sinus is in front, with the meningeal branch of the ascending pharyngeal artery, and is directed obliquely downward and backward; the lateral sinus is situated at the back part of the fora-
men with a meningeal branch of the occipital artery, and between the two are the glossopharyngeal, pneumogastric, and spinal accessory nerves. These three sets of structures are divided from each other by two processes of fibrous tissue. The junction of the sinuses takes place superficial to the nerves, so that these latter lie a little internal to the venous channels in the foramen (see Fig. 386). These sinuses are semicylindrical in form.

The Transverse Sinus, or basilar sinus, consists of several interlacing veins between the layers of the dura mater over the basilar process of the occipital bone, which serve to connect the two inferior petrosal sinuses. With them the anterior spinal veins communicate.

Emissary Veins.—The emissary veins are vessels which pass through apertures in the cranial wall and establish communications between the sinuses inside the skull and the veins external to it. Some of these are always present, others only occasionally so. They vary much in size in different individuals. The principal emissary veins are the following: 1. A vein, almost always present, which passes through the mastoid foramen and connects the lateral sinus with the posterior auricular or with an occipital vein. 2. A vein which passes through the parietal foramen and connects the superior longitudinal sinus with the veins of the scalp. 3. A plexus of minute veins which pass through the anterior condylid foramen and connect the occipital sinus with the vertebral vein and deep veins of the neck. 4. An inconstant vein which passes through the posterior condylid foramen and connects the lateral sinus with the deep veins of the neck. 5. One or two veins of considerable size which pass through the foramen ovale and connect the cavernous sinus with the pterygoid and pharyngeal plexuses. 6. Two or three small veins which pass through the foramen lacerum medium and connect the cavernous sinus with the pterygoid and pharyngeal plexuses. 7. There is sometimes a small...
vein passing through the foramen of Vesalius connecting the same parts. 8. A plexus of veins passing through the carotid canal and connecting the cavernous sinus with the internal jugular vein.

**Surgical Anatomy.**—These emissary veins are of great importance in surgery. In addition to them there are, however, other communications between the intra- and extra-cranial circulation, as, for instance, the communication of the angular and supra-orbital veins with the ophthalmic vein at the inner angle of the orbit (page 653), and the communication of the veins of the scalp with the diploic veins (page 658). Through these communications inflammatory processes commencing on the outside of the skull may travel inward, leading to osteo-phlebitis of the diploë and inflammation of the membranes of the brain. To this must be attributed one of the principal dangers of scalp wounds and other injuries of the scalp.

By means of these emissary veins blood may be abstracted almost directly from the intracranial circulation. For instance, leeches applied behind the ear abstract blood almost directly from the lateral sinus through the vein passing through the mastoid foramen. Again, epistaxis in children will frequently relieve severe headache, the blood which flows from the nose being derived from the longitudinal sinus by means of the vein which passes through the foramen caecum, which is another communication between the intracranial and extracranial circulation which is constantly found in children.

**VEINS OF THE UPPER EXTREMITY AND THORAX.**

The veins of the Upper Extremity are divided into two sets, **superficial** and **deep**.

The **Superficial Veins** are placed immediately beneath the integument between the two layers of superficial fascia.

The **Deep Veins** accompany the arteries, and constitute the venae comites of those vessels.

Both sets of vessels are provided with valves, which are more numerous in the deep than in the superficial.

The superficial veins of the upper extremity are—the

- Superficial veins of the Hand.
- Anterior Ulnar.
- Posterior Ulnar.
- Common Ulnar.
- Radial.
- Median.
- Median Basilic.
- Median Cephalic.
- Basilar.
- Cephalic.

The **Superficial Veins of the Hand and Fingers** are principally situated on the
dorsal surface, and form two plexuses, an inner and outer, on the back of the hand. The inner plexus is formed by the veins from the little finger (vena salva
tella), the ring finger, and the ulnar side of the middle finger; from it the anterior and posterior ulnar veins are derived. The outer plexus is formed by veins from the thumb, the index finger, and radial side of the middle finger; from it the radial vein is derived. These two plexuses communicate on the back of the hand, forming the superficial arch of veins in this situation. The superficial veins from the palm of the hand form a plexus in front of the wrist, from which the median vein is derived.

The **Anterior Ulnar Vein** commences on the anterior surface of the ulnar side of the hand and wrist, and ascends along the anterior surface of the ulnar side of the forearm to the bend of the elbow, where it joins with the posterior ulnar vein to form the common ulnar. Occasionally it opens separately into the median basilic vein. It communicates with branches of the median vein in front and with the posterior ulnar behind.

The **Posterior Ulnar Vein** commences on the posterior surface of the ulnar side of the wrist. It runs on the posterior surface of the ulnar side of the forearm, and just below the elbow unites with the anterior ulnar vein to form the common ulnar, or else joins the median basilic to form the basilic. It communicates with the deep veins of the palm by a branch which emerges from beneath the Abductor minimi digitii muscle.

The **Common Ulnar** is a short trunk which is not constant. When it exists it is formed by the junction of the two preceding veins, and, passing upward and outward, joins the median basilic to form the basilic vein. When it does not exist the anterior and posterior ulnar veins open separately into the median basilic vein.

The **Radial Vein** commences from the dorsal surface of the wrist, communicating with the deep veins of the palm by a branch which passes through the first interosseous space. It forms a large vessel, which ascends along the radial side of the forearm and receives numerous veins from both its surfaces. At the bend of the elbow it unites with the median cephalic to form the cephalic vein.

The **Median Vein** ascends on the front of the forearm, and communicates with the anterior ulnar and radial veins. At the bend of the elbow it receives a branch of communication from the deep veins, and divides into two branches, the median cephalic and median basilic, which diverge from each other as they ascend.

The **Median Cephalic**, usually smaller of the two, passes outward in the groove between the Supinator longus and Biceps muscles, and joins with the radial to form the cephalic vein. The branches of the external cutaneous nerve pass beneath this vessel.

The **Median Basilic Vein** passes obliquely inward, in the groove between the Biceps and Pronator radii teres, and joins the common ulnar to form the basilic. This vein passes in front of the brachial artery, from which it is separated by a fibrous expansion (the bicipital fasia) which is given off from the tendon of the Biceps to the fascia covering the Flexor muscles of the forearm. Filaments of the internal cutaneous nerve pass in front as well as behind this vessel.1

1 Cruveilhier says: “Numerous varieties are observed in the disposition of the veins of the elbow; sometimes the common median vein is wanting; but in those cases its two branches are furnished by the radial vein, and the cephalic is almost always in a rudimentary condition. In other cases only two veins are found at the bend of the elbow, the radial and ulnar, which are continuous, without any demarcation, with the cephalic and basilic.”
no uncommon result of this practice. Another disadvantage is, that the median basilic is crossed by some of the branches of the internal cutaneous nerve, and these may be divided in the operation, giving rise to "traumatic neuralgia of extreme intensity" (Tillaux).

The Basilic Vein is of considerable size, formed by the coalescence of the common ulnar vein with the median basilic. It passes upward along the inner side of the Biceps muscle, pierces the deep fascia a little below the middle of the arm, and, ascending in the course of the brachial artery, terminates in the axillary vein, which receives, a little higher up, the brachial venæ comites.

The Cephalic Vein courses along the outer border of the Biceps muscle, lying in the same groove with the upper external cutaneous branch of the musculo-spiral nerve, to the upper third of the arm; it then passes in the interval between the Pectoralis major and Deltoid muscles, lying in the same groove with the descending branch of the acromial-thoracic artery. It pierces the costo-coracoid membrane, and terminates in the axillary vein just below the clavicle. This vein is occasionally connected with the external jugular or subclavian by a branch which passes from it upward in front of the clavicle.

The Deep Veins of the Upper Extremity follow the course of the arteries, forming their venæ comites. They are generally two in number, one lying on each side of the corresponding artery, and they are connected at intervals by short transverse branches.

There are two digital veins accompanying each artery along the sides of the fingers: these, uniting at their base, pass along the interosseous spaces in the palm, and terminate in the two venæ comites which accompany the superficial palmar arch. Branches from these vessels on the radial side of the hand accompany the superficialis volae, and on the ulnar side terminate in the deep ulnar veins. The deep ulnar veins, as they pass in front of the wrist, communicate with the interosseous and superficial veins, and at the elbow unite with the deep radial veins to form the venæ comites of the brachial artery.

The Interosseous Veins accompany the anterior and posterior interosseous arteries. The anterior interosseous veins commence in front of the wrist, where they communicate with the deep radial and ulnar veins; at the upper part of the forearm they receive the posterior interosseous veins, and terminate in the venæ comites of the ulnar artery.

The Deep Palmar Veins accompany the deep palmar arch, being formed by tributaries which accompany the ramifications of that vessel. They communicate with the deep ulnar veins at the inner side of the hand, and on the outer side terminate in the venæ comites of the radial artery. At the wrist they receive a dorsal and a palmar tributary from the thumb, and unite with the deep radial veins. Accompanying the radial artery, these vessels terminate in the venæ comites of the brachial artery.

The Brachial Veins are placed one on each side of the brachial artery, receiving tributaries corresponding with the branches given off from that vessel; just above the lower margin of the tendon of the Latissimus dorsi they empty into the axillary vein.

These deep veins have numerous anastomoses, not only with each other, but also with the superficial veins.

The Axillary Vein is of large size, and is the continuation of the basilic vein, receiving the venæ comites of the brachial artery. It commences at the lower part of the axillary space, increases in size as it ascends by receiving tributaries corresponding with the branches of the axillary artery, and terminates immediately beneath the clavicle at the lower border of the first rib, where it becomes the subclavian vein. This vessel is covered in front by the Pectoral muscles and costo-coracoid membrane, and lies on the thoracic side of the axillary artery, which it partially overlaps. Near its termination it receives the cephalic vein. This vein is provided with a pair of valves opposite the lower border of the Subscapularis muscle; valves are also found at the termination of the cephalic and subcapular veins.
Surgical Anatomy.—There are several points of surgical interest in connection with the axillary vein. Being more superficial, larger, and slightly overlapping the axillary artery, it is more liable to be wounded in the operation of extirpation of the axillary glands, especially as these glands, when diseased, are apt to become adherent to the vessel. When wounded there is always a danger of air being drawn into its interior, and death resulting. This is due not only to the fact that it is near the thorax, and therefore liable to be influenced by the respiratory movements, but also because it is adherent by its anterior surface to the costo-costal membrane, and therefore if wounded is likely to remain patent and favor the chance of air being sucked in. This adhesion of the vein to the fascia prevents its collapsing, and therefore favors the furious bleeding which takes place in these cases.

To avoid wounding the axillary vein in the extirpation of cancerous glands from the axilla, no sharp cutting instruments should be used after the axillary cavity has been freely exposed, and care should be taken to use no undue force in isolating the glands. Should the vein be so imbedded in the malignant deposit that the latter cannot be removed without taking away a part of the vein, this must be done, the vessel having been first ligatured above and below.

The Subclavian Vein, the continuation of the axillary, extends from the lower border of the first rib to the inner end of the sterno-clavicular articulation, where it unites with the internal jugular to form the innominate vein. It is in relation, in front, with the clavicle and Subclavius muscle; behind, with the subclavian artery, from which it is separated internally by the Scalenus anticus muscle and phrenic nerve. Below, it rests in a depression on the first rib and upon the pleura. Above, it is covered by the cervical fascia and integument.

The subclavian vein occasionally rises in the neck to a level with the third part of the subclavian artery, and in two instances has been seen passing with this vessel behind the Scalenus anticus. This vessel is usually provided with valves about an inch from its termination in the innominate, just external to the entrance of the external jugular vein.

Tributaries.—It receives the external and anterior jugular veins and a small branch from the cephalic, outside the Scalenus, and on the inner side of that muscle the internal jugular vein. At the angle of junction with the internal jugular the left subclavian vein receives the thoracic duct, while the right subclavian vein receives the right lymphatic duct.

The Innominate or Brachio-cephalic Veins (Fig. 388) are two large trunks, placed one on each side of the root of the neck, and formed by the union of the internal jugular and subclavian veins of the corresponding side.

The Right Innominate Vein is a short vessel, an inch in length, which commences at the inner end of the clavicle, and, passing almost vertically downward, joins with the left innominate vein just below the cartilage of the first rib, close to the right border of the sternum, to form the superior vena cava. It lies superficial and external to the innominate artery; on its right side the pleura is interposed between it and the apex of the lung. This vein, at the angle of junction of the internal jugular with the subclavian, receives the right vertebral vein, and, lower down, the right internal mammary, right inferior thyroid, and sometimes the right superior intercostal veins.

The Left Innominate Vein, about two and a half inches in length, and larger than the right, passes from left to right across the upper and front part of the chest, at the same time inclining downward, to unite with its fellow of the opposite side, forming the superior vena cava. It is in relation, in front, with the first piece of the sternum, from which it is separated by the Sterno-hyoid and Sterno-thyroid muscles, the thymus gland or its remains, and some loose areolar tissue. Behind, it lies across the roots of the three large arteries arising from the arch of the aorta. This vessel is joined by the left vertebral, left internal mammary, left inferior thyroid, and the left superior intercostal veins, and occasionally some thymic and pericardiac veins. There are no valves in the innominate veins.

Peculiarities.—Sometimes the innominate veins open separately into the right auricle; in such cases the right vein takes the ordinary course of the superior vena cava; but the left vein, after communicating by a small branch with the right one, passes in front of the root of the left lung, and, turning to the back of the heart, receives the cardiac veins and terminates in the back of the right auricle. This occasional condition of the veins in the adult is a regular one in the fetus at an early period, and the two vessels are persistent in birds and some mammalia. The
subsequent changes which take place in these vessels are the following: The communicating branch between the two trunks enlarges and forms the future left innominate vein; the remaining part of the left trunk is obliterated as far as the heart, where it remains pervious and forms the coronary sinus: a remnant of the obliterated vessel is seen in adult life as a fibrous band passing along the back of the left auricle and in front of the root of the left lung, called by Mr. Marshall the vestigial fold of the pericardium.

The internal mammary veins, two in number to each artery, follow the course of that vessel, and receive corresponding branches. The two veins of each side unite into a single trunk, which terminates in the corresponding innominate vein.

The inferior thyroid veins, two, frequently three or four, in number, arise in the venous plexus on the thyroid body, communicating with the middle and superior thyroid veins. The left one descends in front of the trachea behind the Sterno-thyroid muscle, communicating with its fellow by transverse branches, and terminates in the left innominate vein. The right one, which is placed a little to the right of the median line, opens into the right innominate vein just at its junction with the superior vena cava. These veins receive oesophageal, tracheal, and inferior laryngeal veins, and are provided with valves at their termination in the innominate veins.

The Superior Intercostal Veins return the blood from the upper intercostal spaces, below the first. The right superior intercostal, much smaller than the left, closely corresponds with the superior intercostal artery, receiving the blood from the second or second and third intercostal spaces, and, passing down-
ward, terminates in the vena azygos major. Occasionally it opens into the right innominate vein.

The left superior intercostal is always larger than the right, but varies in size in different subjects, being small when the left upper azygos vein is large, and vice versa. It is usually formed by branches from two or three upper intercostal spaces below the first, and, passing across the arch of the aorta, terminates in the left innominate vein. The left bronchial vein and the left superior phrenic open into it.

The Superior Vena Cava receives the blood which is conveyed to the heart from the whole of the upper half of the body. It is a short trunk, varying from two inches and a half to three inches in length, formed by the junction of the two innominate veins. It commences immediately below the cartilage of the first rib close to the sternum on the right side, and, descending vertically, enters the pericardium about an inch and a half above the heart, and terminates in the upper part of the right auricle opposite the upper border of the third left costal cartilage. In its course it describes a slight curve, the convexity of which is turned to the right side.

Relations.—In front, with the pericardium and process of cervical fascia which is continuous with it: this separates it from the thymus gland and from the sternum; behind, with the root of the right lung; on its right side, with the phrenic nerve and right pleura; on its left side, with the commencement of the innominate artery and ascending part of the aorta. The portion contained within the pericardium is covered by the serous layer of that membrane in its anterior three-fourths. It receives the vena azygos major just before it enters the pericardium, and several small veins from the pericardium and parts in the mediastinum. The superior vena cava has no valves.

The Azygos Veins connect together the superior and inferior vena cavae, taking the place of those vessels in that part of the chest occupied by the heart.

The larger, or right azygos vein (vena azygos major), commences opposite the first or second lumbar vertebra by a branch from the right lumbar veins (the ascending lumbar); sometimes by a branch from the right renal vein or from the inferior vena cava. It enters the thorax through the aortic opening in the Diaphragm, and passes along the right side of the vertebral column to the fourth dorsal vertebra, where it arches forward over the root of the right lung, and terminates in the superior vena cava just before that vessel enters the pericardium. Whilst passing through the aortic opening of the Diaphragm it lies with the thoracic duct on the right side of the aorta, and in the thorax it lies upon the intercostal arteries on the right side of the aorta and thoracic duct, and is partly covered by pleura.

Tributaries.—It receives, excepting those of the first three spaces, the intercostal veins of the right side, the vena azygos minor, the left upper azygos vein, several oesophageal, mediastinal, and pericardial veins; near its termination, the right bronchial vein; and generally the right superior intercostal vein. A few imperfect valves are found in this vein, but its tributaries are provided with complete valves.

The intercostal veins on the left side, below the two or three upper intercostal spaces, form two trunks, named the left lower and the left upper azygos veins.

The left lower, or smaller azygos vein (vena azygos minor), commences in the lumbar region by a branch from one of the lumbar veins (ascending lumbar) or from the left renal. It passes into the thorax through the left crus of the Diaphragm, and, ascending on the left side of the spine as high as the seventh or eighth dorsal vertebra, passes across the column, behind the aorta and thoracic duct, to terminate in the right azygos vein. It receives the four or five lower intercostal veins of the left side, and some oesophageal and mediastinal veins.

The left upper azygos vein varies according to the size of the left superior intercostal, with which it communicates above. It receives veins from the intercostal spaces between the left superior intercostal vein and highest tributary of the left lower azygos. They are usually two or three in number,
and join to form a trunk which ends in the right azygos vein or in the left lower azygos. It sometimes receives the left bronchial vein. When this vein is small or altogether wanting, the left superior intercostal vein will extend as low as the fifth or sixth intercostal space.¹

**Surgical Anatomy.**—In obstruction of the superior vena cava the azygos veins are one of the principal means by which the venous circulation is carried on, connecting as they do the superior and inferior vena cava, and communicating with the common iliac veins by the ascending lumbar veins, and with many of the tributaries of the inferior vena cava.

The *bronchial veins* return the blood from the substance of the lungs; that of the right side opens into the vena azygos major near its termination; that of the left side, into the left superior intercostal vein or left upper azygos vein.

**THE SPINAL VEINS.**

The numerous venous plexuses placed upon and within the spine may be arranged into four sets:

1. Those placed on the exterior of the spinal column (*the dorsi-spinal veins*).
2. Those situated in the interior of the spinal canal, between the vertebrae and the theca vertebrales (*meningo-rachidian veins*).
3. The veins of the bodies of the vertebrae (*vena basis vertebrae*).
4. The veins of the spinal cord (*medulli-spinal*).

1. The **Dorsi-spinal Veins** commence by small branches which receive their blood from the integument of the back of the spine and from the muscles in the vertebral grooves. They form a complicated network, which surrounds the spinous processes, the laminae, and the transverse and articular processes of all the vertebrae. At the bases of the transverse processes they communicate, by means of ascending and descending branches, with the veins surrounding the contiguous vertebrae, and they join with the veins in the spinal canal by branches which perforate the ligamenta subflava. Other branches pass obliquely forward, between the transverse processes, and communicate with the intraspinal veins through the intervertebral foramina. They terminate by joining the vertebral

¹ For an account of the arrangement of the azygos and superior intercostal veins in a number of consecutive cases from the same dissecting-room, see a paper by Mr. B. G. Morison (*Journal of Anatomy and Physiology*, vol. xiii. p. 340). The most important difference between his description and that in the text is, that he always found two superior intercostal veins on both sides, the vein from the first space being separate, and joining the corresponding innominate vein. The lower (and larger) superior intercostal vein he describes as opening into the azygos on the right and innominate on the left side.
THE SPINAL VEINS.

669

veins in the neck, the intercostal veins in the thorax, and the lumbar and sacral veins in the loins and pelvis.

2. The Meningo-rachidian Veins.—The principal veins contained in the spinal canal are situated between the theca vertebralis and the vertebrae. They consist of two longitudinalplexuses, one of which runs along the posterior surface of the bodies of the vertebrae (anterior longitudinal spinal veins). The other plexus (posterior longitudinal spinal veins) is placed on the inner or anterior surface of the laminae of the vertebrae.

The Anterior Longitudinal Spinal Veins consist of two large, tortuous veins which extend along the whole length of the vertebral column, from the foramen magnum where they communicate by a venous ring around that opening, to the base of the coccyx, being placed one on each side of the posterior surface of the bodies of the vertebrae along the margin of the posterior common ligament. These veins communicate together opposite each vertebra by transverse trunks which pass beneath the ligament, and receive the large vena basis vertebrarum from the interior of the body of each vertebra. The anterior longitudinal spinal veins are least developed in the cervical and sacral regions. They are not of uniform size throughout, being alternately enlarged and constricted. At the intervertebral foramina they communicate with the dorsi-spinal veins, and with the vertebral veins in the neck, with the intercostal veins in the dorsal region, and with the lumbar and sacral veins in the corresponding regions.

The Posterior Longitudinal Spinal Veins, smaller than the anterior, are situated one on each side, between the inner surface of the laminae and the theca vertebralis. They communicate (like the anterior) opposite each vertebra by transverse trunks, and with the anterior longitudinal veins by lateral transverse branches which pass from behind forward. These veins, by branches which perforate the ligamenta subita, join with the dorsi-spinal veins. From them branches are given off which pass through the intervertebral foramina and join the vertebral, intercostal, lumbar, and sacral veins.

3. The Veins of the Bodies of the Vertebrae (vena basis vertebrarum) emerge from the foramina on their posterior surface, and join the transverse trunk connecting the anterior longitudinal spinal veins. They are contained in large, tortuous channels in the substance of the bones, similar in every respect to those found in the diploë of the cranial bones. These canals lie parallel to the upper and lower surface of the bones. They commence by small openings on the front and sides of the bodies of the vertebrae, through which communicating branches from the veins external to the bone pass into its substance, and converge to the principal canal, which is sometimes double toward its posterior part, and open into the corresponding transverse branch uniting the anterior longitudinal veins. They become greatly developed in advanced age.

4. The Veins of the Spinal Cord (medulli-spinal) consist of a minute, tortuous,
venous plexus which covers the entire surface of the cord, being situated between the pia mater and arachnoid. These vessels emerge chiefly from the median furrows, and are largest in the lumbar region. Near the base of the skull they unite and form two or three small trunks, which communicate with the vertebral veins, and then terminate in the inferior cerebellar veins or in the inferior petrosal sinuses. Each of the spinal nerves is accompanied by a branch as far as the intervertebral foramina, where they join the other veins from the spinal canal.

There are no valves in the spinal veins.

**VEINS OF THE LOWER EXTREMITY, ABDOMEN, AND PELVIS.**

The Veins of the Lower Extremity are subdivided, like those of the upper, into two sets, superficial and deep, the superficial veins being placed beneath the integument, between the two layers of superficial fascia, the deep veins accompanying the arteries and forming the venous comites of those vessels. Both sets of veins are provided with valves, which are more numerous in the deep than in the superficial set. These valves are also more numerous in the lower than in the upper limb.

The **Superficial Veins of the Lower Extremity** are the *internal* or *long saphenous* and the *external* or *short saphenous*.

On the dorsum of the foot is a venous arch situated in the superficial structures over the anterior extremities of the metatarsal bones. It has its convexity directed forward, and receives digital tributaries from the upper surface of the toes; at its concavity it is joined by numerous small veins which form a plexus on the dorsum of the foot. The arch terminates internally in the long saphenous, externally in a short saphenous vein.

The **internal or long saphenous vein** (Fig. 391) commences at the inner side of the arch on the dorsum of the foot; it ascends in front of the inner malleolus and along the inner side of the leg, behind the inner margin of the tibia, accompanied by the internal saphenous nerve. At the knee it passes backward behind the inner condyle of the femur, ascends along the inside of the thigh, and, passing through the saphenous opening in the fascia lata, terminates in the femoral vein about an inch and a half below Poupart’s ligament. This vein receives in its course cutaneous tributaries from the leg and thigh, and at the saphenous opening the superficial epigastric, superficial circumflex iliac, and external pudic veins. The veins from the inner and back part of the thigh frequently unite to form a large vessel, which enters the main trunk near the saphenous opening; and sometimes those on the outer side of the thigh join to form another large vessel; so that occasionally three large veins are seen converging from different parts of the thigh toward the saphenous opening. The internal saphenous vein communicates in the foot with the internal plantar vein; in the leg, with the posterior tibial veins by branches which perforate the tibial origin of the Soleus muscle, and also with the anterior tibial veins; at the knee, with the articular veins; in the thigh, with the femoral vein by one or more branches. The valves in this vein vary from two to six in number; they are more numerous in the thigh than in the leg.

The **external or short saphenous vein** (Fig. 392) commences at the outer side of the arch on the dorsum of the foot; it ascends behind the outer malleolus, and along the outer border of the tendo Achillis, across which it passes at an acute angle to reach the middle line of the posterior aspect of the leg. Passing directly upward, it perforates the deep fascia in the lower part of the popliteal space, and terminates in the popliteal vein, between the heads of the Gastrocnemius muscle. It receives numerous large tributaries from the back part of

1 Mr. Gay calls attention to the fact that the external saphenous vein often (he says invariably) penetrates the fascia at or about the point where the tendon of the Gastrocnemius commences, and runs below the fascia in the rest of its course, or sometimes among the muscular fibres, to join the popliteal vein. (See Gay on Varicose Disease of the Lower Extremities, p. 24, where there is also a careful and elaborate description of the branches of the saphena veins.)
the leg, and communicates with the deep veins on the dorsum of the foot and behind the outer malleolus. Before it perforates the deep fascia it gives off a communicating branch, which passes upward and inward to join the internal saphenous vein. This vein has a variable number of valves, from three to nine (Gay), one of which is always found near its termination in the popliteal vein. The external saphenous nerve lies close beside this vein.

**Surgical Anatomy.**—The saphenous veins are of considerable surgical importance, since a varicose condition of these vessels is more frequently met with than of those in other parts of the body, except perhaps the spermatic and hemorrhoidal veins. The course of the internal saphenous is in front of the tip of the malleolus, over the subcutaneous surface of the lower end of the tibia, and then along the internal border of this bone to the back part of the internal condyle of the femur, whence it follows the course of the Sartorius muscle, and is represented on the surface by a line drawn from the posterior border of the Sartorius on a level with the internal condyle to the saphenous opening. The short saphenous lies behind the external malleolus, and from this follows the middle line of the calf to just below the ham. It is not generally so apparent beneath the skin as the internal saphenous. Both these veins in the leg are accompanied by nerves, the internal saphenous being joined by its companion nerve just below the level of the knee-joint. No doubt much of the pain of varicose veins in the leg is due to this fact. On the Continent the internal saphenous vein as it rests on the tibia just above the malleolus is sometimes selected for venesection.

The Deep Veins of the Lower Extremity accompany the arteries and their branches, and are called the *vena comites* of those vessels.

The external and internal plantar veins unite to form the posterior tibial. They accompany the posterior tibial artery and are joined by the peroneal veins.

The anterior tibial veins are formed by a continuation upward of the vena comites of the dorsalis pedis artery. They pass between the tibia and fibula, through the large oval aperture above the interosseous membrane, and form, by their junction with the posterior tibial, the popliteal vein.

The valves in the deep veins are very numerous.

The Popliteal Vein is formed by the junction of the vena comites of the anterior and posterior tibial vessels; it ascends through the popliteal space to the tendinous aperture in the Adductor magnus, where it becomes the femoral vein. In the lower part of its course it is placed internal to the artery; between the
heads of the Gastrocnemius it is superficial to that vessel; but above the knee-joint it is close to its outer side. It receives the sural veins from the Gastrocnemius muscle, the articular veins, and the external saphenous. The valves in this vein are usually four in number.

The Femoral Vein accompanies the femoral artery through the upper two-thirds of the thigh. In the lower part of its course it lies external to the artery; higher up it is behind it; and at Poupart's ligament it lies to its inner side and on the same plane. It receives numerous muscular tributaries: the profunda femoris and deep external pudic veins join it near Poupart's ligament and about an inch and a half below the internal saphenous vein. The valves in this vein are four or five in number.

The External Iliac Vein commences at the termination of the femoral, beneath the crural arch, and, passing upward along the brim of the pelvis, terminates opposite the sacro-iliac synchondrosis by uniting with the internal iliac to form the common iliac vein. On the right side it lies at first along the inner side of the external iliac artery, but as it passes upward gradually inclines behind it. On the left side it lies altogether on the inner side of the artery. It receives, immediately above Poupart's ligament, the deep epigastric and deep circumflex iliac veins and a small pubic vein, corresponding to the pubic branch of the obturator artery. According to Friedreich, it frequently contains one, and sometimes two valves.

The Deep Epigastric Veins.—Two veins accompany the deep epigastric artery; they usually unite into a single trunk before their termination in the external iliac vein.

The Deep Circumflex Iliac Veins.—Two veins accompany the deep circumflex iliac artery. These unite into a single trunk which crosses the external iliac artery just above Poupart's ligament and terminates in the external iliac vein.

The Internal Iliac Vein is formed by the venae comites of the branches of the internal iliac artery, the umbilical arteries excepted. It receives the blood from the exterior of the pelvis by the gluteal, sciatic, internal pudic, and obturator veins, and from the organs in the cavity of the pelvis by the haemorrhoidal and vesico-prostatic plexuses in the male, and the uterine and vaginal plexuses in the female. The vessels forming these plexuses are remarkable for their large size, their frequent anastomoses, and the number of valves which they contain. The internal iliac vein lies at first on the inner side, and then behind the internal iliac artery, and terminates opposite the sacro-iliac articulation by uniting with the external iliac to form the common iliac vein. This vessel has no valves.

The internal pudic veins (venae comites) have the same course as the internal pudic artery. They receive tributaries corresponding to the branches of the artery, except the tributary corresponding to the dorsal artery of the penis; that is, the dorsal vein of the penis, which opens into the prostatic plexus.

The haemorrhoidal plexus surrounds the lower end of the rectum, being formed by the superior haemorrhoidal veins (tributaries of the inferior mesenteric), and the middle and inferior haemorrhoidal, which terminate in the internal iliac. The portal and general venous systems have a free communication by means of the branches composing this plexus.

Surgical Anatomy.—The veins of this plexus are apt to become dilated and varicose and form piles. This is partly due to the free communication between the portal and systemic circulation which here exists, so that any obstruction to the flow of blood through either the inferior vena cava or its main tributaries, or through the portal vein, tends to produce passive congestion of this plexus. The condition is also partly due to the fact that the vessels are contained in very loose, lax connective tissue, so that they get less support from surrounding structures than most other veins, and are less capable of resisting increased blood-pressure. And, finally, the condition is favored by gravitation, inasmuch as the portal vein contains no valves.
The vesico-prostatic plexus surrounds the neck and base of the bladder and prostate gland. It communicates with the hemorrhoidal plexus behind, and receives the dorsal vein of the penis, which enters the pelvis beneath the subpubic ligament. This plexus is supported upon the sides of the bladder by a reflection of the pelvic fascia. The veins composing it are very liable to become varicose, and often contain hard, earthy concretions, called phleboliths.

**Surgical Anatomy.**—This plexus is wounded in the lateral operation of lithotomy, and it is through it that septic matter finds its way into the general circulation after this operation.

The dorsal vein of the penis is a vessel of large size which returns the blood from the body of that organ. At first it consists of two branches, which are contained in the groove on the dorsum of the penis, and it receives veins from the glans, the corpus spongiosum, and numerous superficial veins; these unite near the root of the penis into a single trunk, which passes through the suspensory ligament of the penis, pierces the triangular ligament beneath the pubic arch, and divides into two branches, which enter the prostatic plexus.

The vaginal plexus surrounds the mucous membrane, being especially developed at the orifice of the vagina; it communicates with the vesical plexus in front, and with the hemorrhoidal plexus behind.

The uterine plexus is situated along the sides and superior angles of the uterus, between the layers of the broad ligament, receiving large venous canals (the uterine sinuses) from the substance of the uterus. The veins composing this plexus anastomose frequently with each other and with the ovarian veins. They are not tortuous like the arteries.

The Common Iliac Veins are formed by the union of the external and internal iliac veins in front of the sacro-iliac articulation: passing obliquely upward toward the right side, they terminate upon the intervertebral substance between the fourth and fifth lumbar vertebrae, where the veins of the two sides unite at an acute angle to form the inferior vena cava. The right common iliac is shorter than the left, nearly vertical in its direction, and ascends behind and then to the outer side of its corresponding artery. The left common iliac, longer and more oblique in its course, is at first situated on the inner side of the corresponding artery, and then behind the right common iliac. Each common iliac receives the ilio-lumbar, and sometimes the lateral sacral, veins. The left receives, in addition, the middle sacral vein. No valves are found in these veins.

The middle sacral veins accompany the corresponding artery along the front of the sacrum, and terminate in the left common iliac vein; occasionally in the angle of junction of the two iliac veins.

**Peculiarities.**—The left common iliac vein, instead of joining with the right in its usual position, occasionally ascends on the left side of the aorta as high as the kidney, where, after receiving the left renal vein, it crosses over the aorta, and then joins with the right vein to form the vena cava. In these cases the two common iliacs are connected by a small communicating branch at the spot where they are usually united.¹

The Inferior Vena Cava returns to the heart the blood from all the parts below the Diaphragm. It is formed by the junction of the two common iliac veins on the right side of the intervertebral substance between the fourth and fifth lumbar vertebrae. It passes upward along the front of the spine on the right side of the aorta, and, having reached the under surface of the liver, is contained in a groove on its posterior surface. It then perforates the central tendon of the Diaphragm, enters the pericardium, where it is covered by its serous layer, and terminates in the lower and back part of the right auricle. At its termination in the auricle it is provided with a valve, the Eustachian, which is of large size during foetal life.

**Relations.**—In front, from below upward, with the mesentery, right spermatic artery, transverse portion of the duodenum, the pancreas, portal vein, and the

¹ See two cases which have been described by Mr. Walsham in the *St. Bartholomew's Hospital Reports*, vols. xvi. and xvii.
posterior surface of the liver, which partly and occasionally completely surrounds it; behind, with the vertebral column, the right crus of the Diaphragm, the right renal and lumbar arteries, right semilunar ganglion; on the left side, with the aorta.

**Tributaries.**—It receives in its course the following veins:

- **Lumbar.**
- **Right Spermatic.**
- **Renal.**
- **Suprarenal.**
- **Phrenic.**
- **Hepatic.**

**Peculiarities.**—In Position.—This vessel is sometimes placed on the left side of the aorta, as high as the left renal veins, after receiving which it crosses over to its usual position on the right side; or it may be placed altogether on the left side of the aorta, as far upward as its termination in the heart: in such cases the abdominal and thoracic viscera, together with the great vessels, are all transposed.

**Point of Termination.**—Occasionally the inferior vena cava joins the right azygos vein, which is then of large size. In such cases the superior cava receives the whole of the blood from the body before transmitting it to the right auricle, except, the blood from the hepatic veins, which passes directly into the right auricle.

The **lumbar veins**, four in number on each side, collect the blood by dorsal tributaries from the muscles and integument of the loins and by abdominal tributaries from the walls of the abdomen, where they communicate with the epigastric veins. At the spine they receive veins from the spinal plexuses, and then pass forward, round the sides of the bodies of the vertebrae beneath the Psoas major, and terminate at the back part of the inferior cava. The left lumbar veins are longer than the right, and pass behind the aorta. The lumbar veins are connected together by a longitudinal vein which passes in front of the transverse processes of the lumbar vertebrae, and is called the ascending lumbar. It forms the most frequent origin of the corresponding vena azygos, and serves to connect the common iliac, ilio-lumbar, lumbar, and azygos veins of the corresponding side of the body.

The **spermatic veins** emerge from the back of the testis, and receive tributaries from the epididymis; they unite and form a convoluted plexus called the **spermatic plexus (plexus pampiniformis)**, which forms the chief mass of the cord: the vessels composing this plexus are very numerous, and ascend along the cord in front of the vas deferens; below the external abdominal ring they unite to form three or four veins, which pass along the spermatic canal, and, entering the abdomen through the internal abdominal ring, coalesce to form two veins, which ascend on the Psoas muscle behind the peritoneum, lying one on each side of the spermatic artery, and unite to form a single vein, which opens on the right side into the inferior vena cava at an acute angle; on the left side into the left renal vein at a right angle. The spermatic veins are provided with valves. The left spermatic vein passes behind the sigmoid flexure of the colon, and is thus exposed to pressure from the contents of that bowel.

**Surgical Anatomy.**—The spermatic veins are very frequently varicose, constituting the disease known as varicocele. Though it is quite possible that the originating cause of this affection may be a congenital abnormality either in the size or number of the veins of the pampiniform plexus, still it must be admitted that there are many anatomical reasons why these veins should become varicose—viz. the imperfect support afforded to them by the loose tissue of the scrotum; their great length; their vertical course; their dependent position; their plexiform arrangement in the scrotum, with their termination in one small vein in the abdomen; their few and imperfect valves; and the fact that they may be subjected to pressure in their passage through the abdominal wall.

The **ovarian veins** are analogous to the spermatic in the male; they form a plexus near the ovary and in the broad ligament and Fallopian tube, communicating with the uterine plexus. They terminate in the same way as the spermatic veins in the male. Valves are occasionally found in these veins. These vessels, like the uterine veins, become much enlarged during pregnancy.

1 Rivington has pointed out that a valve is usually found at the orifices of both the right and left spermatic veins. When no valves exist at the opening of the left spermatic vein into the left renal vein, valves are generally present in the left renal vein within a quarter of an inch from the orifice of the spermatic vein (Journal of Anatomy and Physiology, vol. vii. p. 163).
The renal veins are of large size, and placed in front of the renal arteries.\(^1\) The left is longer than the right, and passes in front of the aorta, just below the origin of the superior mesenteric artery. It receives the left spermatic, the left inferior phrenic, and, generally, the left suprarenal veins. It opens into the vena cava a little higher than the right.

The suprarenal veins terminate, on the right side, in the vena cava; on the left side, in the left renal or phrenic vein.

The phrenic veins follow the course of the phrenic arteries. The two superior, of small size, accompany the phrenic nerve and comes nervi phrenici artery, and join the internal mammary. The two inferior phrenic veins follow the course of the phrenic arteries, and terminate, the right in the inferior vena cava, the left in the left renal vein.

The hepatic veins commence in the substance of the liver, in the capillary terminations of the portal vein and hepatic artery: these tributaries, gradually uniting, usually form three large veins, which converge toward the posterior surface of the liver and open into the inferior vena cava, whilst that vessel is situated in the groove at the back part of this organ. Of these three veins, one from the right, and another from the left lobe, open obliquely into the inferior vena cava, that from the middle of the organ and lobulus Spigelii having a straight course. The hepatic veins run singly, and are in direct contact with the hepatic tissue. They are destitute of valves.

The Portal System of Veins.

The portal venous system is composed of four large veins which collect the venous blood from the viscera of digestion. The trunk formed by their union (vena portae) enters the liver and ramifies throughout its substance, and its branches, again emerging from that organ as the hepatic veins, terminate in the inferior vena cava. The branches in this vein are in all cases single and destitute of valves.

The veins forming the portal system are—the

The superior mesenteric vein returns the blood from the small intestines and from the cecum and ascending and transverse portions of the colon, corresponding with the distribution of the branches of the superior mesenteric artery. The large trunk formed by the union of these branches ascends along the right side and in front of the corresponding artery, passes in front of the transverse portion of the duodenum, and unites, behind the upper border of the pancreas, with the splenic vein to form the vena portae. It receives the right gastro-epiploic vein.

The splenic vein commences by five or six large branches which return the blood from the substance of the spleen. These, uniting, form a single vessel, which passes from left to right, grooving the upper and back part of the pancreas below the artery, and terminates at its greater end by uniting at a right angle with the superior mesenteric to form the vena portae. The splenic vein is of large size, and not tortuous like the artery. It receives the vasa brevia from the left extremity of the stomach, the left gastro-epiploic vein, pancreatic branches from the pancreas, the pancreatico-duodenal vein, and the inferior mesenteric vein.

The inferior mesenteric vein returns the blood from the rectum, sigmoid flexure, and descending colon, corresponding with the ramifications of the branches of the inferior mesenteric artery. Ascending beneath the peritoneum in the lumbar region, it passes behind the transverse portion of the duodenum and pancreas and terminates in the splenic vein. Its hemorrhoidal branches inosculate with those

---

\(^1\)The student may observe that all veins above the Diaphragm, which do not lie on the same plane as the arteries which they accompany, lie in front of them, and that all veins below the Diaphragm, which do not lie on the same plane as the arteries which they accompany, lie behind them, except the renal and profunda femoris vein.
of the internal iliac, and thus establish a communication between the portal and the general venous system.\(^1\)

The **gastric veins** are two in number: one, a small vein, corresponds to the pyloric branch of the hepatic artery; the other, considerably larger, corresponds to the gastric artery. The former (**pyloric, Walsham**) runs along the lesser cur-

\[\text{Fig. 393.—Portal vein and its branches.}\]

**Note.**—In this diagram the right gastro-epiploic vein opens into the splenic vein; generally it empties itself into the superior mesenteric, close to its termination.

vature of the stomach toward the pyloric end, receives branches from the pylorus and duodenum, and ends in the vena portae. The latter (**coronary, Walsham**) begins near the pylorus, runs along the lesser curvature of the stomach toward the

\(^1\) Besides this anastomosis between the portal vein and the branches of the vena cava, other anastomoses between the portal and systemic veins are formed by the communication between the gastric veins and the esophageal veins, which empty themselves into the vena azygos minor; between the left renal vein and the veins of the intestines, especially of the colon and duodenum; between the veins of the round ligament of the liver and the portal veins; and between the superficial branches of the portal veins of the liver and the phrenic veins, as pointed out by Mr. Kiernan. (See *Physiological Anatomy*, by Todd and Bowman, 1859, vol. ii. p. 348.)
esophageal opening, and then curves downward and backward between the folds of the lesser omentum, to end in the vena portae.

The **Portal Vein** is formed by the junction of the superior mesenteric and splenic veins, their union taking place in front of the vena cava and behind the upper border of the great end of the pancreas. Passing upward through the right border of the lesser omentum to the under surface of the liver, it enters the transverse fissure, where it is somewhat enlarged, forming the *sinus* of the portal vein, and divides into two branches which accompany the ramifications of the hepatic artery and hepatic duct throughout the substance of the liver. Of these two branches, the right is the larger, but the shorter, of the two. The portal vein is about three or four inches in length, and, whilst contained in the lesser omentum, lies behind and between the hepatic duct and artery, the former being to the right, the latter to the left. These structures are accompanied by filaments of the hepatic plexus of nerves and numerous lymphatics, surrounded by a quantity of loose areolar tissue (*capsule of Glisson*), and placed between the layers of the lesser omentum. The vena portae receives the gastric and cystic veins: the latter vein sometimes terminates in the right branch of the vena portae. Within the liver the portal vein receives the blood from the branches of the hepatic artery.

**THE CARDIAC VEINS.**

The veins which return the blood from the substance of the heart are—

- Anterior Cardiac Vein.
- Posterior Cardiac Vein.
- Left Cardiac Veins.
- Right Cardiac Veins.
- Right or Small Coronary Sinus.
- Left or Great Coronary Sinus.

*Vénæ Thebesii.*

The **Anterior Cardiac Vein** (sometimes called *Great Cardiac Vein*) is a vessel of considerable size which commences at the apex of the heart and ascends along the anterior interventricular groove to the base of the ventricles. It then curves to the left side, around the auriculo-ventricular groove, between the left auricle and ventricle, to the back part of the heart, and opens into the great coronary sinus, its aperture being guarded by two valves. It receives, in its course, tributaries from both ventricles, but especially the left, and also from the left auricle; one of these, ascending along the thick margin of the left ventricle, is of considerable size. The vessels joining it are provided with valves.

The **Middle Cardiac Vein** commences by small tributaries at the apex of the heart, communicating with those of the preceding. It ascends along the posterior interventricular groove to the base of the heart, and terminates in the great coronary sinus, its orifice being guarded by a valve. It receives the veins from the posterior surface of both ventricles.

The **Left** or **Posterior Cardiac Veins** are three or four small vessels which collect the blood from the posterior surface of the left ventricle, and open into the lower border of the great coronary sinus.

The **Right** or **Anterior Cardiac Veins** are three or four small vessels which collect the blood from the anterior surface of the right ventricle. One of these (the *vein of Galen*), larger than the rest, runs along the right border of the heart. They open separately into the lower part of the right auricle.

The **Right** or **Small Coronary Sinus** runs along the groove between the right auricle and ventricle, to open into the right extremity of the great coronary sinus. It receives blood from the back part of the right auricle and ventricle.

The **Left** or **Great Coronary Sinus** is that portion of the anterior cardiac vein which is situated in the posterior part of the left auriculo-ventricular groove. It is about an inch in length, presents a considerable dilatation, and is covered by the muscular fibres of the left auricle. It receives the veins enumerated above, and an *oblique vein* from the back part of the left auricle, the remnant of the obliterated left innominate trunk of the foetus, described by Mr. Marshall. The
great coronary sinus terminates in the right auricle between the inferior vena cava and the auriculo-ventricular aperture, its orifice being guarded by a semilunar fold of the lining membrane of the heart, the \textit{coronary valve}. All the veins joining this vessel, excepting the oblique vein above mentioned, are provided with valves.

The \textit{Venae Thebesii} are numerous minute veins, which return the blood directly from the muscular substance, without entering the venous current. They open by minute orifices (\textit{foramina Thebesii}) on the inner surface of the right auricle. Similarly minute veins are said to open into the left auricle and both ventricles.
THE LYMPHATICS.

The Lymphatics have derived their name from the appearance of the fluid contained in their interior (lympha, water). They are also called absorbents, from the property they possess of absorbing certain materials from the tissues and conveying them into the circulation.

The lymphatic system includes not only the lymphatic vessels and the glands through which they pass, but also the lacteal or chyliferous vessels. The lacteals are the lymphatic vessels of the small intestine, and differ in no respect from the lymphatics generally, excepting that they contain a milk-white fluid, the chyle, during the process of digestion, and convey it into the blood through the thoracic duct.

The lymphatics are exceedingly delicate vessels, the coats of which are so transparent that the fluid they contain is readily seen through them. They retain a nearly uniform size, being interrupted at intervals by constrictions, which give them a knotted or beaded appearance. These constrictions are due to the presence of valves in their interior. Lymphatics have been found in nearly every texture and organ of the body which contain blood-vessels. Such non-vascular structures as cartilage, the nails, cuticle, and hair have none, but with these exceptions it is probable that eventually all parts will be found to be permeated by these vessels.

The lymphatics are arranged into a superficial and deep set. The superficial lymphatics, on the surface of the body, are placed immediately beneath the integument, accompanying the superficial veins; they join the deep lymphatics in certain situations by perforating the deep fascia. In the interior of the body they lie in the submucous areolar tissue throughout the whole length of the gastrointestinal and genito-urinary tracts, and in the subserous tissue in the cranial, thoracic, and abdominal cavities. The method of their origin has been described along with the other details of their minute anatomy (page 86). Here it will be sufficient to say that a plexiform network of minute lymphatics may be found interspersed among the proper elements and blood-vessels of the several tissues, the vessels composing which, as well as the meshes between them, are much larger than those of the capillary plexus. From these networks small vessels emerge, which pass either to a neighboring gland or to join some larger lymphatic trunk. The deep lymphatics, fewer in number and larger than the superficial, accompany the deep blood-vessels. Their mode of origin is probably similar to that of the superficial vessels. The lymphatics of any part or organ exceed the veins in number, but in size they are much smaller. Their anastomoses also, especially those of the large trunks, are more frequent, and are effected by vessels equal in diameter to those which they connect, the continuous trunks retaining the same diameter.

The lymphatic or absorbent glands, named also conglobate glands, are small, solid, glandular bodies situated in the course of the lymphatic and lacteal vessels. In size they vary from a hemp-seed to an almond, and their color, on section, is of a pinkish-gray tint, excepting the bronchial glands, which in the adult are mottled with black. Each gland has a layer or capsule of cellular tissue investing it, from which prolongations dip into its substance, forming partitions. The lymphatic and lacteal vessels pass through these bodies in their passage to the thoracic and lymphatic ducts. A lymphatic or lacteal vessel, previous to
entering a gland, divides into several small branches, which are named *afferent vessels*. As they enter their external coat becomes continuous with the capsule of the gland, and the vessels, much thinned, and consisting only of their internal or endothelial coat, pass into the gland, and branch out upon and in the tissue of the capsule, these branches opening into the lymph-sinuses of the gland. From these sinuses fine branches proceed to form a plexus, the vessels of which unite to form a single *efferent vessel*, which, on emerging from the gland, is again invested with an external coat. (Further details on the minute anatomy of the lymphatic vessels and glands will be found in the chapter on General Anatomy.)

**THE THORACIC DUCT.**

The thoracic duct (Fig. 394) conveys the great mass of lymph and chyle into the blood. It is the common trunk of all the lymphatic vessels of the body, excepting those of the right side of the head, neck, and thorax, and right upper extremity, the right lung, right side of the heart, and the convex surface of the liver. It varies in length from fifteen to eighteen inches in the adult, and extends from the second lumbar vertebra to the root of the neck. It commences in the abdomen by a triangular dilatation, the *receptaculum chyli* (reservoir or cistern of Pecquet), which is situated upon the front of the body of the second lumbar vertebra, to the right side and behind the aorta, by the side of the right crus of the Diaphragm. It ascends into the thorax through the aortic opening in the Diaphragm, lying to the right of the aorta, and is placed in the posterior mediastinum in front of the vertebral column, lying between the aorta and vena azygos major. Opposite the fourth dorsal vertebra it inclines toward the left side, and ascends behind the arch of the aorta on the left side of the oesophagus, and behind the first portion of the left subclavian artery, to the upper orifice of the thorax. Opposite the seventh cervical vertebra it turns outward and then curves downward over the subclavian artery and in front of the Scalenus anticus muscle, so as to form an arch, and terminates in the left...
subclavian vein at its angle of junction with the left internal jugular vein. The thoracic duct, at its commencement, is about equal in size to the diameter of a goosequill, diminishes considerably in its calibre in the middle of the thorax, and is again dilated just before its termination. It is generally flexuous in its course, and constricted at intervals so as to present a varicose appearance. The thoracic duct not unfrequently divides in the middle of its course into two branches of unequal size, which soon reunite, or into several branches, which form a plexiform interlacement. It occasionally divides, at its upper part, into two branches, of which the one on the left side terminates in the usual manner, while that on the right opens into the right subclavian vein, in connection with the right lymphatic duct. The thoracic duct has numerous valves throughout its whole course, but they are more numerous in the upper than in the lower part: at its termination it is provided with a pair of valves, the free borders of which are turned toward the vein, so as to prevent the passage of venous blood into the duct.

Tributaries.—The thoracic duct, at its commencement, receives four or five large trunks from the abdominal lymphatic glands, and also the trunk of the lactic vessels. Within the thorax it is joined by the lymphatic vessels from the left half of the wall of the thoracic cavity, the lymphatics from the sternal and intercostal glands, those of the left lung, left side of the heart, trachea, and esophagus; and, just before its termination, it receives the lymphatics of the left side of the head and neck and left upper extremity.

Structure (Fig. 61).—The thoracic duct is composed of three coats, which differ in some respects from those of the lymphatic vessels. The internal coat consists of a single layer of flattened lanceolate-shaped endothelial cells with serrated borders; of a subendothelial layer, similar to that found in the arteries; and an elastic fibrous coat, the fibres of which run in a longitudinal direction. The middle coat consists of a longitudinal layer of white connective tissue with elastic fibres, external to which are several laminae of muscular tissue, the fibres of which are for the most part disposed transversely, but some are oblique or longitudinal and intermixed with elastic fibres. The external coat is composed of areolar tissue, with elastic fibres and isolated fasciculi of muscular fibres.

The Right Lymphatic Duct is a short trunk, about half an inch in length and a line or a line and a half in diameter. It terminates in the right subclavian vein at its angle of junction with the right internal jugular vein. Its orifice is guarded by two semilunar valves, which prevent the passage of venous blood into the duct.

Tributaries.—It receives the lymph from the right side of the head and neck, the right upper extremity, the right side of the thorax, the right lung and right side of the heart, and from part of the convex surface of the liver.

LYMPHATICS OF THE HEAD, FACE, AND NECK.

The Lymphatic Glands of the Head (Fig. 395) are of small size, few in number, and confined to its posterior region. They are the occipital and posterior auricular. The occipital set are placed at the back of the head along the attachment of the Occipito-frontalis muscle. The posterior auricular set are placed near the upper end of the Sterno-mastoid muscle. Both these sets of glands are affected in cutaneous eruptions and other diseases of the scalp. In the face the superficial lymphatic glands are more numerous: they are the parotid, some of which are superficial, and others deeply placed in the substance of the parotid gland; the zygomatic, situated under the zygoma; the buccal, on the surface of the Buccinator muscle; and the internal maxillary, the largest, beneath the ramus of the lower jaw.

The lymphatic vessels of the scalp are divided into an anterior and a posterior set, which follow the course of the temporal and occipital vessels. The temporal set accompany the temporal artery in front of the ear, to the parotid lymphatic glands, from which they proceed to the lymphatic glands of the neck. The occipital set follow the course of the occipital artery, descend to the occipital
and posterior auricular lymphatic glands, and from thence join the cervical glands.

The **Lymphatic Vessels of the Face** are divided into two sets, *superficial* and *deep*.

The **superficial lymphatic vessels of the face** are more numerous than those of the head, and commence over its entire surface. Those from the frontal region accompany the frontal vessels; they then pass obliquely across the face, running with the facial vein, pass through the buccal glands on the surface of the Buccinator muscle, and join the submaxillary lymphatic glands. The latter receive the lymphatic vessels from the lips, and are often found enlarged in cases of malignant disease of those parts.

The **deep lymphatic vessels of the face** are derived from the pituitary membrane of the nose, the mucous membrane of the mouth and pharynx, and the contents of the temporal and orbital fossae; they accompany the branches of the internal maxillary artery, and terminate in the internal maxillary and cervical lymphatic glands.

The **lymphatic vessels of the cranium** consist of two sets, the *meningeal* and *cerebral*. The *meningeal lymphatics* accompany the meningeal vessels, escape through foramina at the base of the skull, and join the deep cervical lymphatic glands. The *cerebral lymphatics* are described by Eshmann as being situated between the arachnoid and pia mater, as well as in the choroid plexuses of the
OF THE NECK.

OF THE NECK.

683

lateral ventricles; they accompany the trunks of the carotid and vertebral arteries, and probably pass through foramina at the base of the skull to terminate in the deep cervical glands. They have not at present been demonstrated in the dura mater or in the substance of the brain.

The Lymphatic Glands of the Neck are divided into two sets, superficial and deep.

The superficial cervical glands may be arranged in three sets: (1) The submaxillary, ten to fifteen in number, situated beneath the body of the lower jaw in the submaxillary triangle; (2) suprathyroid, situated in the middle line of the neck, between the anterior bellies of the two digastric muscles; and (3) cervical, placed in the course of the external jugular vein between the Platysma and deep fascia. They are most numerous at the root of the neck, in the triangular interval between the clavicle, the Sterno-mastoid, and the Trapezius, where they are continuous with the axillary glands. A few small glands are also found on the front and sides of the larynx.

The deep cervical glands (Fig. 396) are numerous and of large size; they form a chain along the sheath of the carotid artery and internal jugular vein, lying by the side of the pharynx, oesophagus, and trachea, and extending from the base of the skull to the thorax, where they communicate with the lymphatic glands in that cavity. They are subdivided into two sets: an upper, ten to twenty in number,
situated about the bifurcation of the common carotid and along the upper part of the internal jugular vein; and a lower, ten to fifteen in number, clustered around the lower part of the internal jugular vein, and extending outward into the suprACLavicular fossa, where they are continuous with the axillary glands. Internally, this set is continuous with the mediastinal glands.

The superficial and deep cervical lymphatic vessels are a continuation of those already described on the cranium and face. After traversing the glands in those regions, they pass through the chain of glands which lie along the sheath of the carotid vessels, being joined by the lymphatics from the pharynx, oesophagus, larynx, trachea, and thyroid gland. At the lower part of the neck, after receiving some lymphatics from the thorax, they unite into a single trunk, which terminates, on the left side, in the thoracic duct; on the right side, in the right lymphatic duct.

Surgical Anatomy.—The cervical glands are very frequently the seat of tuberculous trouble. This condition is most usually set up by some lesion in those parts from which they receive their lymph. This excites some inflammation, which subsequently takes on a tuberculous character. It is very desirable, therefore, for the surgeon, in dealing with these cases, to possess a knowledge of the relation of the respective groups of glands to the periphery. The following table is extracted from Mr. Treves’s work on Scrofula and its Gland Diseases:

Scalp.—Posterior part = suboccipital and mastoid glands. Frontal and parietal portions = parotid glands.

Lymphatic vessels from the scalp also enter the superficial cervical set of glands.

Skin of face and neck = submaxillary, parotid, and superficial cervical glands.

External ear = superficial cervical glands.

Lower lip = submaxillary and suprathyoid glands.

Buccal cavity = submaxillary and upper set of deep cervical glands.

Gums of lower jaw = submaxillary glands.

Tongue.—Anterior portion = suprathyoid and submaxillary glands. Posterior portion = upper set of deep cervical glands.

Tonsils and palate = upper set of deep cervical glands.

Pharynx.—Upper part = parotid and retro-pharyngeal glands. Lower part = upper set of deep cervical glands.

Larynx, orbit, and roof of mouth = upper set of deep cervical glands.

Nasal fossae = retro-pharyngeal glands, upper set of deep cervical glands. Some lymphatic vessels from posterior part of the fossae enter the parotid glands.

LYMPHATICS OF THE UPPER EXTREMIT Y.

The Lymphatic Glands of the Upper Extremity (Fig. 397) are divided into two sets, superficial and deep.

The superficial lymphatic glands are few and of small size. There are occasionally two or three in front of the elbow, and one or two above the internal condyle of the humerus, near the basilic vein.

The deep lymphatic glands are few in number, and are subdivided into those in the forearm, the arm, and the axilla. In the forearm a few small ones are occasionally found in the course of the radial and ulnar vessels. In the arm there is a chain of small glands along the inner side of the brachial artery. One, sometimes two, fairly constant glands are situated a little above and in front of the inner condyle of the humerus. In the axilla they are of large size, and usually ten or twelve in number. A chain of these glands surrounds the axillary vessels, imbedded in a quantity of loose areolar tissue; they receive the lymphatic vessels from the arm; others are dispersed in the areolar tissue of the axilla; the remainder are arranged in two series, a small chain running along the lower border of the Pectoralis major, receiving the lymphatics from the front of the chest and mamma; and others are placed along the lower margin of the posterior wall of the axilla, which receive the lymphatics from the integument of the back. Two or three subclavian lymphatic glands are placed immediately beneath the clavicle; it is through these that the axillary and deep cervical glands communicate with each other.

Surgical Anatomy.—In malignant diseases, tumors, or other affections implicating the upper part of the back and shoulder, the front of the chest and mamma, the upper part of the
OF THE UPPER EXTREMITY.

front and side of the abdomen, or the hand, forearm, and arm, the axillary glands are liable to be found enlarged.

The lymphatic vessels of the upper extremity are divided into two sets, superficial and deep.

The superficial lymphatic vessels of the upper extremity commence on the fingers. Two vessels running along either side of each finger, one on the palmar and the other on the dorsal surface. Those on the palmar surface form an arch in the

![Diagram](image-url)

**Fig. 397.**—The superficial lymphatics and glands of the upper extremity.

palm of the hand, from which are derived two sets of vessels, which pass up the forearm, taking the course of the subcutaneous veins. The lymphatics from the dorsal surface of the fingers form a plexus on the back of the hand, and, winding around the inner and outer borders of the forearm, unite with those in front. Those from the inner border of the hand accompany the ulnar veins along the inner side of the forearm to the bend of the elbow, where they are joined by some lymphatics from the outer side of the forearm: they then follow the course of the basilic vein, communicate with the glands immediately above the elbow, and terminate in the axillary glands, joining with the deep lymphatics. The superficial lymphatics from
the outer and back part of the hand accompany the radial veins to the bend of the elbow. They are less numerous than the preceding. At the bend of the elbow the greater number join the basilic group; the rest ascend with the cephalic vein on the outer side of the arm, some crossing the upper part of the Biceps obliquely, to terminate in the axillary glands, whilst one or two accompany the cephalic vein in the cellular interval between the Pectoralis major and Deltoid, and enter the subclavian lymphatic glands.

The deep lymphatic vessels of the upper extremity accompany the deep blood-vessels. In the forearm they consist of four sets, corresponding with the radial, ulnar, and interosseous arteries; they pass through the glands occasionally found in the course of those vessels, and communicate at intervals with the superficial lymphatics. In their course upward some of them pass through the glands which lie upon the brachial artery; they then enter the axillary and subclavian glands, and at the root of the neck terminate on the left side in the thoracic duct, and on the right side in the right lymphatic duct.

LYMPHATICS OF THE LOWER EXTREMITY.

The Lymphatic Glands of the Lower Extremity are divided into two sets, superficial and deep. The superficial are confined to the inguinal region, forming the superficial inguinal lymphatic glands.

The superficial inguinal lymphatic glands, placed immediately beneath the integument, are of large size, and vary from eight to ten in number. They are divisible into two groups: an upper oblique set, disposed irregularly along Poupart's ligament, which receive the lymphatic vessels from the integument of the scrotum, penis, parietes of the abdomen, perineal and gluteal regions, and the mucous membrane of the urethra; and an inferior vertical set, which surround the saphenous opening in the fascia lata, a few being sometimes continued along the saphenous vein to a variable extent. This latter group receive the superficial lymphatic vessels from the lower extremity.

Surgical Anatomy.—These glands frequently become enlarged in diseases implicating the parts from which their lymphatics originate. Thus in malignant or syphilitic affections of the prepuce and penis, or of the labia majora in the female, in cancer serotum, in abscess in the perineum, or in any other diseases affecting the integument and superficial structures in those parts, or the subumbilical part of the abdominal wall or the gluteal region, the upper chain of glands is almost invariably enlarged, the lower chain being implicated in diseases affecting the lower limb.

The deep lymphatic glands are the anterior tibial, popliteal, deep inguinal, gluteal, and ischiatic.

The anterior tibial gland is not constant in its existence. It is generally found by the side of the anterior tibial artery, upon the interosseous membrane at the upper part of the leg. Occasionally, two glands are found in this situation.

The popliteal glands, four or five in number, are of small size; they surround the popliteal vessels, imbedded in the cellular tissue and fat of the popliteal space.

The deep inguinal glands are placed beneath the deep fascia around the femoral artery and vein. They are of small size, and communicate with the superficial inguinal glands through the saphenous opening.

The gluteal and ischiatic glands are placed, the former above, the latter below, the Pyriformis muscle, resting on their corresponding vessels as they pass through the great sacro-sciatic foramen.

The Lymphatic Vessels of the Lower Extremity, like the veins, may be divided into two sets, superficial and deep.

The superficial lymphatic vessels are placed beneath the integument in the superficial fascia, and are divisible into two groups: an internal group, which follow the course of the internal saphenous vein; and an external group, which accompany the external saphenous. The internal group, the larger, commence on the inner side and dorsum of the foot; they pass, some in front and some behind
Superficial inguinal glands.

the inner ankle, run up the leg with the internal saphenous vein, pass with it behind the inner condyle of the femur, and accompany it to the groin, where they terminate in the group of superficial inguinal lymphatic glands which surround the saphenous opening. Some of the efferent vessels from these glands pierce the cribriform fascia and sheath of the femoral vessels, and terminate in a lymphatic gland contained in the femoral canal, thus establishing a communication between the lymphatics of the lower extremity and those of the trunk; others pierce the fascia lata and join the deep inguinal glands. The external group arise from the outer side of the foot, ascend in front of the leg, and, just below the knee, cross the tibia from without inward, to join the lymphatics on the inner side of the thigh. Others commence on the outer side of the foot, pass behind the outer malleolus, and accompany the external saphenous vein along the back of the leg, where they enter the popliteal glands.

The deep lymphatic vessels of the lower extremity are few in number and accompany the deep blood-vessels. In the leg they consist of three sets, the anterior tibial, peroneal, and posterior tibial, which accompany the corresponding blood-vessels, two or three to each artery; they ascend with the blood-vessels and enter the lymphatic glands in the popliteal space; the efferent vessels from these glands accompany the femoral vein and join the deep inguinal glands; from these, the vessels pass beneath Poupart's ligament and communicate with the chain of glands surrounding the external iliac vessels.

The deep lymphatic vessels of the gluteal and ischiatic regions follow the course of the blood-vessels, and join the gluteal and ischiatic glands at the great sacro-sciatic foramen.

LYMPHATICS OF THE PELVIS AND ABDOMEN.

The Lymphatic Glands in the Pelvis are the external iliac, the internal iliac, and the sacral. Those of the abdomen are the lumbar glands.

The external iliac glands form an uninterrupted chain round the external iliac vessels, three being placed round the commencement of the vessels just behind the
crural arch. They communicate below with the deep inguinal lymphatic glands, and above with the lumbar glands.

The internal iliac glands surround the internal iliac vessels; they receive the lymphatic vessels corresponding to the branches of the internal iliac artery, and communicate with the lumbar glands.

The sacral glands occupy the sides of the anterior surface of the sacrum, some

being situated in the meso-rectal fold. These and the internal iliac glands are affected in malignant disease of the bladder, rectum, or uterus.

The lumbar glands are very numerous; they are situated on the front of the lumbar vertebrae, surrounding the common iliac vessels, the aorta, and vena cava; they receive the lymphatic vessels from the lower extremities and pelvis, as well as from the testes and some of the abdominal viscera: the efferent vessels from these glands unite into a few large trunks, which, with the lacteals, form the commence-
ment of the thoracic duct. In addition to these there are a few small lateral lum-
bar glands which lie between the transverse processes of the vertebrae, behind the Psoas muscle, and receive lymphatics from the back. In some cases of malignant disease these glands become enormously enlarged, completely surrounding the aorta and vena cava, and occasionally greatly contracting the calibre of those vessels. In all cases of malignant disease of the testes and in malignant disease of the lower limb, before any operation is attempted, careful examination of the abdomen should be made, in order to ascertain if any enlargement exists; and if any should be detected, all operative measures should be avoided as fruitless.

The Lymphatic Vessels of the Abdomen and Pelvis may be divided into two sets, superficial and deep.

The superficial lymphatic vessels of the walls of the abdomen and pelvis follow the course of the superficial blood-vessels. Those derived from the integument of the lower part of the abdomen below the umbilicus follow the course of the superficial epigastric vessels and converge to the superior group of the superficial inguinal glands; a deeper set accompany the deep epigastric vessels, and communicate with the external iliac glands. The superficial lymphatics from the sides of the lumbar part of the abdominal wall wind round the crest of the ilium, accompanying the superficial circumflex iliac vessels, to join the superior group of the superficial inguinal glands; the greater number, however, run backward along with the ilio-lumbar and lumbar vessels, to join the lateral lumbar glands.

The superficial lymphatic vessels of the gluteal region turn horizontally round the outer side of the nates, and join the superficial inguinal glands.

The superficial lymphatic vessels of the scrotum and perineum follow the course of the external pudic vessels, and terminate in the superficial inguinal glands.

The superficial lymphatic vessels of the penis occupy the sides and dorsum of the organ, the latter receiving the lymphatics from the skin covering the glans penis; they all converge to the upper chain of the superficial inguinal glans. The deep lymphatic vessels of the penis follow the course of the internal pudic vessels, and join the internal iliac glands.

In the female the lymphatic vessels of the mucous membrane of the labia, nymphæ, and clitoris terminate in the upper chain of the inguinal glands.

The deep lymphatic vessels of the abdomen and pelvis take the course of the principal blood-vessels. Those of the parietes of the pelvis, which accompany the gluteal, ischiatic, and obturator vessels, follow the course of the internal iliac artery, and ultimately join the lumbar lymphatics.

The efferent vessels from the inguinal glands enter the pelvis beneath Poupart's ligament, where they lie in close relation with the femoral vein; they then pass through the chain of glands surrounding the external iliac vessels, and finally terminate in the lumbar glands. They receive the deep epigastric and circumflex iliac lymphatics.

The lymphatic vessels of the bladder arise from the entire surface of the organ; the greater number run beneath the peritoneum on its posterior surface, and, after passing through the lymphatic glands in that situation, join with the lymphatics from the prostate and vesiculae seminales, and enter the internal iliac glands.

The lymphatic vessels of the rectum are of large size; after passing through some small glands that lie upon its outer wall and in the meso-rectum they pass to the sacral glands.

The lymphatic vessels of the uterus consist of two sets, superficial and deep, the former being placed beneath the peritoneum, the latter in the substance of the organ. The lymphatics of the cervix uteri, together with those from the vagina, enter the internal iliac and sacral glands; those from the body and fundus of the uterus pass outward in the broad ligaments, and, being joined by the lymphatics

1 Curnow states that they are confined to the base of the organ.
from the ovaries, broad ligaments, and Fallopian tubes, ascend with the ovarian vessels to open into the lumbar glands. In the unimpregnated uterus they are small, but during gestation they become very greatly enlarged.

The **lymphatic vessels of the testis** consist of two sets, superficial and deep: the former commence on the surface of the tunica vaginalis, the latter in the epidermis and body of the testis. They form several large trunks which ascend with the spermatic cord, and, accompanying the spermatic vessels into the abdomen, terminate into the lumbar glands; hence the enlargement of these glands in malignant disease of the testis.

The **lymphatic vessels of the kidney** arise on the surface, and also in the interior of the organ; they join at the hilum, and, after receiving the lymphatic vessels from the ureter and suprarenal capsules, open into the lumbar glands.

The **lymphatic vessels of the liver** are divisible into two sets, superficial and deep. The former arise in the subperitoneal areolar tissue over the entire surface of the organ. Those on the convex surface may be divided into four groups: 1. Those which pass from behind forward, consisting of three or four branches, which ascend in the longitudinal ligament and unite to form a single trunk, which passes up between the fibres of the Diaphragm, behind the ensiform cartilage, to enter the anterior mediastinal glands, and finally ascend to the root of the neck, to terminate in the right lymphatic duct. 2. Another group, which also incline from behind forward, are reflected over the anterior margin of the liver to its under surface, and from thence pass along the longitudinal fissure to the glands in the gastro-hepatic omentum. 3. A third group incline outward to the right lateral ligament, and, uniting into one or two large trunks, pierce the Diaphragm, and run along its upper surface to enter the anterior mediastinal glands, or, instead of entering the thorax, turn inward across the crus of the Diaphragm and open into the commencement of the thoracic duct. 4. The fourth group incline outward from the surface of the left lobe of the liver to the left lateral ligament, pierce the Diaphragm, and, passing forward, terminate in the glands in the anterior mediastinum.

The **superficial lymphatics on the under surface of the liver** are divided into three sets: 1. Those on the right side of the gall-bladder enter the lumbar glands. 2. Those surrounding the gall-bladder form a remarkable plexus; they accompany the hepatic vessels, and open into the glands in the gastro-hepatic omentum. 3. Those on the left of the gall-bladder pass to the oesophageal glands and to the glands which are situated along the lesser curvature of the stomach.

The **deep lymphatics** accompany the branches of the portal vein and the hepatic artery and duct through the substance of the liver; passing out at the transverse fissure, they enter the lymphatic glands along the lesser curvature of the stomach and behind the pancreas, or join with one of the lacteal vessels previous to its termination in the thoracic duct.

The **lymphatic glands of the stomach** are of small size; they are placed along the lesser and greater curvatures, some within the gastro-splenic omentum, whilst others surround the cardiac and pyloric orifices.

The **lymphatic vessels of the stomach** consist of two sets, superficial and deep, the former originating in the subserous, and the latter in the submucous, coat. They follow the course of the blood-vessels, and may consequently be arranged into three groups: The first group accompany the gastric vessels along the lesser curvature, receiving branches from both surfaces of the organ, and pass to the glands around the pylorus. The second group pass from the great end of the stomach, accompanying the vasa brevia, and enter the splenic lymphatic glands. The third group run along the greater curvature with the right gastro-epiploic vessels, and terminate at the root of the mesentery in one of the principal lacteal vessels.

The **lymphatic glands of the spleen** occupy the hilum. Its lymphatic vessels consist of two sets, superficial and deep: the former are placed beneath its peritoneal covering, the latter in the substance of the organ; they accompany the
blood-vessels, passing through a series of small glands, and, after receiving the lymphatics from the pancreas, ultimately pass into the thoracic duct.

**THE LYMPHATIC SYSTEM OF THE INTESTINES.**

The lymphatic glands of the small intestine are placed between the layers of the mesentery, occupying the meshes formed by the superior mesenteric vessels, and hence called mesenteric glands. They vary in number from a hundred to a hundred and fifty, and in size from that of a pea to that of a small almond. These glands are most numerous, and largest above, near the duodenum, and below, opposite the termination of the ileum in the colon. This latter group becomes enlarged and infiltrated with deposit in cases of fever accompanied with ulceration of the intestines.

The lymphatic glands of the large intestine are much less numerous than the mesenteric glands; they are situated along the vascular arches formed by the arteries previous to their distribution, and even sometimes upon the intestine itself. They are fewest in number along the transverse colon, where they form an uninterrupted chain with the mesenteric glands.

The lymphatic vessels of the small intestine are called lacteals, from the milk-white fluid they usually contain: they consist of two sets, superficial and deep, the former lie between the layers of the muscular coat and between the muscular and peritoneal coats, taking a longitudinal course along the outer side of the intestine; the latter occupy the submucous tissue, and course transversely round the intestine, accompanied by the branches of the mesenteric vessels; they pass between the layers of the mesentery, enter the mesenteric glands, and finally unite to form two or three large trunks which terminate in the thoracic duct.

The lymphatic vessels of the large intestine consist of two sets: those of the caecum, ascending and transverse colon, which, after passing through their proper glands, enter the mesenteric glands; and those of the descending colon, sigmoid flexure, and rectum, which pass to the lumbar glands.

**THE LYMPHATICS OF THE THORAX.**

The Lymphatic Glands of the Thoracic Wall are the intercostal, internal mammary, anterior mediastinal, and posterior mediastinal.

The intercostal glands are small, irregular in number, and situated on each side of the spine, near the costo-vertebral articulations, some being placed between the two planes of intercostal muscles.

The internal mammary glands are placed at the anterior extremity of each intercostal space, by the side of the internal mammary vessels.

The anterior mediastinal glands are placed in the loose areolar tissue of the anterior mediastinum, some lying upon the Diaphragm in front of the pericardium, and others round the great vessels at the base of the heart.

The posterior mediastinal glands are situated in the areolar tissue in the posterior mediastinum, forming a continuous chain by the side of the aorta and œsophagus; they communicate on each side with the intercostal, below with the lumbar, and above with the deep cervical glands.

The Superficial Lymphatic Vessels of the Front of the Thorax run across the great Pectoral muscle, and those on the back part of this cavity lie upon the Trapezius and Latissimus dorsi; they all converge to the axillary glands. The lymphatics from the greater part of the mammary gland pass outward to the lower border of the Pectoralis major muscle, where they enter a chain of small glands situated in the axillary space along the lower border of its anterior boundary. Some few lymphatics from the inner side of the mammary gland pass through the intercostal spaces to reach the anterior mediastinal glands.

The Deep Lymphatic Vessels of the Thoracic Wall are the intercostal, internal mammary, and diaphragmatic.

The intercostal lymphatic vessels follow the course of the intercostal vessels,
receiving lymphatics from the intercostal muscles and pleura; they pass backward to the spine, and unite with lymphatics from the back part of the thorax and spinal canal. After traversing the intercostal glands, they pass down the spine and terminate in the thoracic duct.

The internal mammary lymphatic vessels follow the course of the internal mammary vessels; they commence in the muscles of the abdomen above the umbilicus, communicating with the epigastric lymphatics, ascend between the fibres of the Diaphragm at its attachment to the ensiform appendix, and in their course behind the costal cartilages are joined by the intercostal lymphatics; they terminate on the right side in the right lymphatic duct, on the left side in the thoracic duct.

The lymphatic vessels of the Diaphragm follow the course of their corresponding vessels, and terminate, some in front in the anterior mediastinal and internal mammary glands, some behind, in the intercostal and posterior mediastinal lymphatics.

The Lymphatic Glands of the Viscera are the bronchial glands.

The bronchial glands are situated round the bifurcation of the trachea and roots of the lungs. They are ten or twelve in number, the largest being placed opposite the bifurcation of the trachea, the smallest round the bronchi and their primary divisions for some little distance within the substance of the lungs. In infancy they present the same appearance as lymphatic glands in other situations; in the adult they assume a brownish tinge, and in old age a deep black color. Occasionally they become sufficiently enlarged to compress and narrow the canal of the bronchi, and they are often the seat of tubercle or cretaceous deposits.

The lymphatic vessels of the lung consist of two sets, superficial and deep: the former are placed beneath the pleura, forming a minute plexus which covers the outer surface of the lung; the latter accompany the blood-vessels and run along the bronchi: they both terminate at the root of the lungs in the bronchial glands. The efferent vessels from these glands, two or three in number, ascend upon the trachea to the root of the neck, traverse the tracheal and esophageal glands, and terminate on the left side in the thoracic duct and on the right side in the right lymphatic duct.

The cardiac lymphatic vessels consist of two sets, superficial and deep: the former arise in the subserous areolar tissue of the surface, and the latter in the deeper tissues of the heart. They follow the course of the coronary vessels: those of the right side unite into a trunk at the root of the aorta, which, ascending across the arch of that vessel, passes backward to the trachea, upon which it ascends, to terminate at the root of the neck in the right lymphatic duct. Those of the left side unite into a single vessel at the base of the heart, which, passing along the pulmonary artery and traversing some glands at the root of the aorta, ascends on the trachea to terminate in the thoracic duct.

The thymic lymphatic vessels arise from the under surface of the thymus gland, and terminate on each side in the internal jugular veins.

The thyroid lymphatic vessels arise from either lateral lobe of this organ: they converge to form a short trunk, which terminates on the right side in the right lymphatic duct, on the left side in the thoracic duct.

The lymphatic vessels of the esophagus form a plexus round that tube, traverse the glands in the posterior mediastinum, and, after communicating with the pulmonary lymphatic vessels near the roots of the lungs, terminate in the thoracic duct.
THE NERVOUS SYSTEM.

The Nervous System is composed—1. Of a series of large centres of nerve-matter, called, collectively, the cerebro-spinal centre or axis. 2. Of smaller centres, termed ganglia. 3. Of nerves, connected either with the cerebro-spinal axis or the ganglia. And 4. Of certain modifications of the peripheral terminations of the nerves, forming the organs of the external senses.

The Cerebro-spinal Centre consists of two parts, the spinal cord and the encephalon; the latter may be subdivided into the cerebrum, the cerebellum, the pons Varolii, and the medulla oblongata.

THE SPINAL CORD AND ITS MEMBRANES.

Dissection.—To dissect the cord and its membranes it will be necessary to lay open the whole length of the spinal canal. For this purpose the muscles must be separated from the vertebral grooves, so as to expose the spinous processes and laminae of the vertebrae; and the latter must be sawn through on each side, close to the roots of the transverse processes, from the third or fourth cervical vertebra above to the sacrum below. The vertebral arches having been displaced by means of a chisel and the separate fragments removed, the dura mater will be exposed, covered by a plexus of veins and a quantity of loose areolar tissue, often infiltrated with serous fluid. The arches of the upper vertebrae are best divided by means of a strong pair of cutting bone-forceps.

MEMBRANES OF THE CORD.

The membranes which envelop the spinal cord are three in number. The most external is the dura mater, a strong fibrous membrane which forms a loose sheath around the cord. The most internal is the pia mater, a cellulo-vascular membrane which closely invests the entire surface of the cord. Between the two is the arachnoid membrane, a non-vascular membrane which envelops the cord and is connected to the pia mater by slender filaments of connective tissue.

The Dura Mater of the cord, continuous with that which invests the brain, is a loose sheath which surrounds the cord, and is separated from the bony walls of the spinal canal by a quantity of loose areolar tissue and a plexus of veins. It is attached to the circumference of the foramen magnum and to the posterior common ligament, especially at the lower end of the spinal canal, by fibrous slips, and extends below as far as the third piece of the sacrum; but beyond this point it is impervious, being continued in the form of a slender cord to the back of the coccyx, where it blends with the periosteum. This sheath is much larger than is necessary for its contents, and its size is greater in the cervical and lumbar regions than in the dorsal. Its inner surface is smooth. On each side may be seen the double openings which transmit the two roots of the corresponding spinal nerve, the fibrous layer of the dura mater being continued in the form of a tubular prolongation on them as they pass through these apertures. On opening the lower part of the dura mater—i.e., below the termination of the cord proper—the roots of the lumbar and sacral nerves are seen. These roots, taken together, form what is known as the cauda equina. In the midst of the cauda equina is a delicate process of gray matter within a tube of pia mater. This is the filum terminale. This comes off from the conus terminalis (Fig. 402) or cone-like ending of the cord, and blends, below, with the slender cord-like prolongation of the dura mater just mentioned. (See page 695.)
The chief peculiarities of the dura mater of the cord, as compared with that investing the brain, are the following:

The dura mater of the cord is not adherent to the bones of the spinal canal, which have an independent periosteum.

It does not send partitions into the fissures of the cord, as in the brain.

Its fibrous lamina do not separate to form venous sinuses, as in the brain.

**Structure.**—The dura mater consists of white fibrous and elastic tissue arranged in bands or lamellae, which, for the most part, are parallel with one another. Its internal surface is covered by a layer of endothelial cells which gives this surface its smooth appearance. It is sparingly supplied with vessels, and some few nerves have been traced into it.

The **Arachnoid** is exposed by slitting up the dura mater and reflecting that membrane to either side (Fig. 400). It is a thin, delicate, tubular membrane which invests the surface of the cord, and is connected to the pia mater by slender filaments of connective tissue. Above, it is continuous with the cerebral arachnoid; on each side it is continued on the various nerves, so as to form a sheath for them as they pass outward to the intervertebral foramina. The outer surface of the arachnoid is in contact with the inner surface of the dura mater, and the two are, here and there, connected together by isolated connective-tissue trabeculae, especially on the posterior surface of the cord. For the most part, however, the membranes are not connected together, and the interval between them is named the **subdural space**. The inner surface of the arachnoid is separated from the pia mater by a considerable interval, which is called the **subarachnoid space**. The space is the largest at the lower part of the spinal canal, and encloses the mass of nerves which form the cauda equina. Superiorly it is continuous with the cranial subarachnoid space, and communicates with the general ventricular cavity of the brain by means of an opening in the pia mater at the inferior boundary of the fourth ventricle (**foramen of Majendie**). It contains an abundant serous secretion, the **cerebro-spinal fluid**. This secretion is sufficient in amount to expand the arachnoid membrane, so as to completely fill up the whole of the space included in the dura mater. The subarachnoid space is occupied by trabeculae of delicate connective tissue, connecting the pia mater on the one hand with the arachnoid membrane on the other. This is named **subarachnoid tissue**. In addition to this it is partially subdivided by a longitudinal membranous partition, which serves to connect the arachnoid with the pia mater, opposite the posterior median fissure. This partition is incomplete and cribiform in structure, consisting of bundles of white fibrous tissue interlacing with each other.

This space is to be regarded as, in reality, a great lymph-space, from which the lymph carried to it by the perivascular lymph-sheath (see page 87) is conveyed back into the circulation.
THE SPINAL CORD. 695

Structure.—The arachnoid is a delicate membrane made up of closely arranged interlacing bundles of connective tissue in several layers.

The Pia Mater of the cord is exposed on the removal of the arachnoid (Fig. 400). It covers the entire surface of the cord, to which it is very intimately adherent, forming its neurilemma, and sending a process downward into its anterior fissure. It also forms a sheath for each of the filaments of the spinal nerves, and invests the nerves themselves. A longitudinal fibrous band extends along the middle line on its anterior surface, called by Haller the linea splendens; and a somewhat similar band, the ligamentum denticulatum, is situated on each side. At the point where the cord terminates the pia mater becomes contracted, and is continued down as a long, slender filament (filum terminale), which descends through the centre of the mass of nerves forming the cauda equina, and is blended with the impervious sheath of dura mater on a level with the third sacral vertebra. It assists in maintaining the cord in its position during the movements of the trunk, and is from this circumstance called the central ligament of the spinal cord. It contains a little gray nervous substance, which may be traced for some distance into its upper part, and is accompanied by a small artery and vein. At the upper part of the cord the pia mater presents a grayish, mottled tint, which is owing to yellow or brown pigment-cells scattered among the elastic fibres.

Structure.—The pia mater of the cord is less vascular in structure, but thicker and denser, than the pia mater of the brain, with which it is continuous. It consists of two layers: an outer composed of bundles of connective-tissue fibres, arranged for the most part longitudinally; and an inner, consisting of stiff bundles of the same tissue, which present peculiar angular bends, and is covered on both surfaces by a layer of endothelium. Between the two layers are a number of cleftlike lymphatic spaces which communicate with the subarachnoid cavity, and a number of blood-vessels which are enclosed in a perivascular sheath, derived from the inner layer of the pia mater, into which the lymphatic spaces open. It is also supplied with nerves, which are derived from the sympathetic.

The Ligamentum Denticulatum (Fig. 400) is a narrow fibrous band, situated on each side of the spinal cord, throughout its entire length, and separating the anterior from the posterior roots of the spinal nerves. It has received its name from the serrated appearance which it presents. Its inner border is continuous with the pia mater at the side of the cord. Its outer border presents a series of triangular, dentated serrations, the points of which are fixed at intervals to the dura mater. These serrations are twenty-one in number on each side, the first being attached to the dura mater, opposite the margin of the foramen magnum between the vertebral artery and the hypoglossal nerve, and the last near the lower end of the cord. Its use is to support the cord in the fluid by which it is surrounded.

THE SPINAL CORD (Fig. 402).

The Spinal Cord (medulla spinalis) is the cylindrical, elongated part of the cerebro-spinal axis which is contained in the vertebral canal. Its length is usually about seventeen or eighteen inches, and its weight, when divested of its membranes and nerves, about one ounce and a half, its proportion to the encephalon being about 1 to 33. It does not nearly fill the canal in which it is contained, its investing membranes being separated from the surrounding walls by areolar tissue and a plexus of veins. It occupies, in the adult, the upper two-thirds of the vertebral canal, extending from the upper border of the atlas to the lower border of the body of the first lumbar vertebra, where it terminates in a slender filament of gray substance, which is continued for some distance into the filum terminale. In the fetus, before the third month, it extends to the bottom of the sacral canal, but after this period it gradually recedes from below, as the growth of the bones composing the canal is more rapid in proportion than that
of the cord, so that in the child at birth the cord extends as far as the third lumbar vertebra. Its position varies also according to the degree of curvature of the spinal column, being raised somewhat in flexion of the spine. On examining its surface it presents a difference in its diameter in different parts, being marked by two enlargements, an upper or cervical, and a lower or lumbar. The cervical enlargement, which is the larger, extends from about the third cervical to the first or second dorsal vertebra: its greatest diameter is in the transverse direction, and it corresponds with the origin of the nerves which supply the upper extremities. The lower, or lumbar, enlargement (intumescentia) is situated opposite the last two or three dorsal vertebrae, its greatest diameter being from before backward. It corresponds with the origin of the nerves which supply the lower extremities. In form the spinal cord is a flattened cylinder (Fig. 402).

Fissures.—It presents on its anterior surface, along the middle line, a longitudinal fissure, the anterior median fissure, and on its posterior surface another fissure, which also extends along the entire length of the cord, the posterior median fissure. These fissures penetrate through the greater part of the thickness of the cord, and incompletely divide the cord into two symmetrical halves, united in the middle line by a transverse band of nervous substance, the commissure.

The Anterior Median Fissure is wider, but of less depth, than the posterior, extending into the cord for about one-third of its thickness, and is deepest at the lower part of the cord. It con-
tains a prolongation from the pia mater, and its floor is formed by the anterior white commissure, which is perforated by numerous blood-vessels passing to the centre of the cord.

The Posterior Median Fissure is not an actual fissure, as the space between the lateral halves of the posterior part of the cord is crossed by connective tissue and numerous blood-vessels, so that no actual hiatus exists, and there is consequently no prolongation of the pia mater into it. It extends into the cord to about one half its depth, and its floor is formed by the posterior gray commissure.

Lateral Fissures.—On each side of the anterior median fissure a linear series of foramina may be observed, indicating the points where the anterior roots of the spinal nerves emerge from the cord. This is called, by some anatomists, the antero-lateral fissure of the cord, although no actual fissure exists in this situation. And on each side of the posterior median fissure, along the line of attachment of the posterior roots of the nerves, a delicate fissure may be seen, leading down to the gray matter which approaches the surface in this situation; this is called the postero-lateral fissure of the spinal cord. On the posterior surface of the spinal cord, between the posterior median and the postero-lateral fissure on each side, is a slight longitudinal furrow (posterior intermediate furrow) marking off two tracts, the posterior median columns. These are most distinct in the cervical region, but are stated by Foville to exist throughout the whole length of the cord.

Columns of the Cord.—Each half of the spinal cord is thus divided into three main columns: an antero-lateral column, a postero-lateral column, and a postero-median column.

The antero-lateral column, which forms rather more than two-thirds of the entire circumference of the cord, includes all the portion of the cord between the anterior median fissure and the postero-lateral fissure.

By some anatomists the antero-lateral column is subdivided into an anterior column, which includes all the portion of the cord between the anterior median fissure and the line from which the anterior roots of the nerves arise; and a lateral column, which includes all the portion between the line of origin of the anterior roots of the spinal nerves and the postero-lateral fissure.

The postero-lateral column is situated between the postero-lateral fissure and the posterior intermediate furrow.

The posterior median column is that narrow segment of the cord which is seen on each side of the posterior median fissure, usually included with the preceding as the posterior column.

Structure of the Cord.—If a transverse section of the spinal cord be made, it will be seen to consist of white and gray nervous substance. The white matter is situated externally, and constitutes the greater part. The gray substance occupies the centre, and is so arranged as to present on the surface of the section two crescentic masses, placed one in each lateral half of the cord, united together by a transverse band of gray matter, the gray commissure. Each crescentic mass has an anterior and posterior horn. The posterior horn is long and narrow, and approaches the surface of the postero-lateral fissure, near which it presents a slight enlargement, the caput cornu: from this it tapers to form the apex cornu, which at the surface of the cord becomes continuous with the fibres of the posterior roots of the spinal nerves. The anterior horn is short and thick, and does not quite reach the surface, but extends toward the point of attachment of the anterior roots of the nerves. Its margin presents a dentate or stellate appearance. Owing to the projections toward the surface of the anterior and posterior horns of the gray matter, each half of the cord is divided, more or less completely, into three columns, anterior, middle, and posterior, the anterior and middle being joined to form the antero-lateral column, as the anterior horn does not quite reach the surface.

The commissure of the spinal cord is composed of white and gray fibres, hence called the white and gray commissures. The white commissure is formed of fibres which, for the most part, pass horizontally between the gray matter of the anterior horn of one side and the anterior white column of the opposite side.
The gray commissure, which connects the two crescentic masses of gray matter, is separated from the bottom of the anterior median fissure by the anterior white commissure. It consists of transverse fibres, with a considerable quantity of neuroglia between them. The fibres when they reach the lateral crescents diverge: some pass backward to the posterior roots; others spread out, at various angles, into the cervix cornu.

Running through the gray commissure of the whole length of the cord is a minute canal, which is barely visible to the naked eye in the human cord, but is proportionally larger in some of the lower vertebrata. It is called the central canal, and opens above into the fourth ventricle, and terminates below in a somewhat dilated extremity. It is lined in the fetus by columnar ciliated epithelium, but in the adult very often the eilia have disappeared, and the canal is filled with their remains. The cells are supported on a layer of neuroglia, which is sometimes called the substantia gelatinosa centralis.

The mode of arrangement of the gray matter, and its amount in proportion to the white, vary in different parts of the cord. Thus, the posterior horns are long and narrow in the cervical region; short and narrower in the dorsal; short, but wider, in the lumbar region. In the cervical region the crescentic portions are small, and the white matter more abundant than in any other region of the cord. In the dorsal region the gray matter is least developed, the white matter being also small in quantity. In the lumbar region the gray matter is more abundant than in any other region of the cord. Toward the lower end of the cord the white matter gradually ceases. The crescentic portions of the gray matter soon blend into a single mass, which forms the only constituent of the extreme point of the cord.

Minute Anatomy of the Cord.—The cord consists of an outer part, composed of medullated nerve-fibres, which is the white substance; and of a central part, the gray matter, both supported in a peculiar kind of tissue, called neuroglia.

The neuroglia consists of a homogeneous transparent matrix, of a network of very delicate fibrillæ, and of small stellate or branched cells, the neuroglia-cells.

In addition to forming a ground substance, in which the nerve-fibres, nerve-cells, and blood-vessels are imbedded, a considerable accumulation of neuroglia takes place in three situations—(1) on the surface of the cord, beneath the pia mater; (2) around the central canal; and (3) in the posterior part of the posterior horn, forming the substantia cinerea gelatinosa.
The white substance of the cord consists of medullated nerve-fibres, with blood-vessels and neuroglia. On transverse section of the white substance of the cord a very striking object is presented. It is seen to be studded all over with minute dots, surrounded by a white area, and this again by a dark circle (Fig. 410). This is due to the longitudinal medullated fibres seen on section. The dot is the axis-cylinder, the white area the substance of Schwann, and the dark circle the tubular membrane of the fibres, which seems to consist of several laminae. Externally, the neuroglia is seen to form a delicate connective sheath round the outer surface of the cord immediately beneath the pia mater, from which numerous septa pass in to separate the respective bundles of fibres and extend between the individual nerve-fibres, acting as a supporting medium in which they are imbedded. Thus it will be seen that the greater bulk of the white matter of the cord is made up of longitudinal medullated fibres, which are arranged in groups forming the antero-lateral and posterior columns.

There are, however, also oblique and transverse fibres in the white substance. These are principally found (1) at the bottom of the anterior median fissure, forming the white commissure, the fibres passing from the gray matter of the anterior horn on one side to the white matter of the anterior column of the opposite side; (2) horizontal or oblique fibres passing from the roots of the nerves into

---

**Fig. 406.** Transverse section through the cervical portion of the spinal cord of the calf. Magnified 40 diameters. (Klein and Noble Smith.)
the gray matter; and (3) fibres leaving the gray matter, and pursuing a longer or shorter horizontal course between the bundles of longitudinal fibres, with which many of them are continuous.

The investigation of pathological lesions has shown that of the main columns of the cord each consists of certain sub-columns or tracts of fibres, for it has been found that separate lesions are strictly limited to certain well-determined parts of the organ without involving neighboring regions. That these parts or fasciculi correspond to so many distinct anatomical systems, each endowed with special functions, seems abundantly proved by the researches of Flechsig and others on the development of the cord during the later periods of utero-gestation and in the newly-born infant. Thus, on either side of the anterior median fissure a portion of the antero-lateral column is divided off as the direct pyramidal tract (fasciculus of Türck), which can be traced to be continuous with the non-decussating fibres of the pyramid of the medulla. The remainder of the antero-lateral column of the cord is formed of six tracts or columns, which, as to actual size, may be divided into three large and three small tracts. The three former are: (1) The crossed pyramidal tract, whose fibres when traced upward form the decussating portion of the pyramid of the medulla oblongata; (2) the direct cerebellar tract, which passes above into the restiform body of the medulla; (3) the antero-lateral ground bundle, the fibres of which are continued into the formatio reticularis of the medulla. The three latter are: (1) The antero-lateral descending cerebellar tract (Loewenthal); (2) the antero-lateral ascending cerebellar tract (Gowers); (3) the tract of Lissauer. For the prolongations of the first two, see Structure of the Medulla. The last is not apparently found in the medulla. All these small tracts occupy the surface of the cord (see Fig. 407).

The posterior column of the cord is divided into two: the portion which lies next the posterior median fissure is called the column of Golt (postero-median), and if traced upward is found to be continuous with the funiculus gracilis of the medulla. The remainder of the posterior column is called the postero-lateral or Burdach's column, and is prolonged into the medulla under the name of funiculus cuneatus.

Collateral Fibres.—The posterior nerve-roots, on entering the cord, separate into the component fibres, each of which bifurcates into an ascending and descending branch, which run upward and downward in the posterior column and in the posterior cornu. Furthermore, each of these fibres before bifurcating and each of its bifurcations gives off at intervals collateral branches, which penetrate the
gray matter and there break up into an arborization of nerve-fibrils which appears to have some, though not direct, connection with a similar arborization of the branched processes from the nerve-cells (see Fig. 411).

The gray substance of the cord occupies its central part in the shape of two crescentic horns, joined together by a commissure. Each of these crescents has an anterior and posterior cornu.

The posterior horn consists of two parts—the caput cornu, or expanded extremity of the horn (Fig. 409), round which is a lighter space or lamina of gelatinous substance; and the cervix cornu, or narrower portion, which connects it with the rest of the gray substance.

The gelatinous substance is a peculiar accumulation of neuroglia (Klein), and has been named by Rolando the substantia cinerea gelatinosa.

The anterior horn of the gray substance in the cervical and lumbar swellings, where it gives origin to the nerves of the extremities, is much larger than in any other region, and contains several distinct groups of large and variously shaped cells.

In addition to this, in certain parts of the cord other horns or projections of the gray matter may be seen on transverse section. One of these, the lateral horn, is found projecting outward from the lateral region of the gray matter on a level with the gray commissure in the cervical and upper part of the dorsal region of the cord; and a second, Clarke's vesicular column, is found on the inner side of the posterior horn near the gray commissure, in the upper cervical or dorsal regions or at the point of exit of the lower lumbar nerves.

The gray commissure is situated behind the white commissure, which separates it from the bottom of the anterior median fissure.

The gray substance of the cord consists of—(1) nerve-fibres of variable but smaller average diameter than those of the columns; (2) nerve-cells of various shapes and sizes, with from two to eight processes; (3) blood-vessels and neuroglia.

The nerve-fibres of the gray matter of the posterior horn are for the most part
composed of a minute and dense network of minute fibrils, which is termed "Gerlach's nerve-network," intermingled with nerves of a larger size. This network is continuous with the medullated fibres of the posterior nerve-roots on the one hand (Deiters), and with the branched processes of the ganglion-cells on the other (Gerlach), so that the ganglion-cells are connected with the medullated fibres of the posterior nerve-roots only indirectly through the nerve-network. The arrangement of the fibres in the anterior horn of the gray matter appears to be somewhat different: here the medullated fibres of the anterior nerve-roots are for the most part directly continuous with the axis-cylinder processes of the ganglion-cells (Fig. 411).

The nerve-cells of the gray matter are of two kinds, large branched nerve-vesicles which are collected into groups, and small round cells which resemble free nuclei and are found scattered throughout the whole of the gray matter.

In the anterior horn is a constant group, situated at the anterior part of the cornu, and sometimes termed the vesicular column of the anterior cornu. It consists of two groups of cells: one mesial, near the anterior column; the other lateral, near the lateral column. At the base of the posterior horn on its inner side, and joining the gray commissure, is a group of nerve-cells, which give rise to the projection mentioned above as being seen on transverse section in the upper part of the cord, which is called Clarke's posterior vesicular column.

At the junction of the anterior and posterior cornu, in the outer portion of the gray matter, is a third group of cells, the tractus intermedia-lateralis. In certain regions of the cord these cells extend in amongst the fibres of the white matter of the lateral column, and give rise to the lateral horn. In addition to these groups a few large scattered cells are found in the posterior horn, extending into the substantia cinerea gelatinosa.

**THE BRAIN AND ITS MEMBRANES.**

**Dissection.**—To examine the brain with its membranes the skull-cap must be removed. In order to effect this, saw through the external table, the section commencing in front, about an inch above the margin of the orbit, and extending, behind, to a level with the occipital protuberance. Then break the internal table with the chisel and hammer, to avoid injuring the investing membranes or brain; loosen and forcibly detach the skull-cap, when the dura mater will be exposed. The adhesion between the bone and the dura mater is very intimate, and much more so in the young subject than in the adult.
MEMBRANES OF THE BRAIN.

The membranes of the brain are the dura mater, arachnoid membrane, and pia mater.

The Dura Mater.

The Dura Mater (Fig. 410) is a thick and dense inelastic fibrous membrane which lines the interior of the skull. Its outer surface is rough and fribillated, and adheres closely to the inner surface of the bones, forming their internal periosteum, this adhesion being most marked opposite the sutures and at the base of the skull. Its inner surface is smooth and lined by a layer of endothelial cells. It sends three processes inward, into the cavity of the skull, for the support and protection of the different parts of the brain, and is prolonged to the outer surface of the skull through the various foramina which exist at the base, and thus becomes continuous with the pericranium; its fibrous layer forms sheaths for the nerves which pass through these apertures. At the base of the skull it sends a fibrous prolongation into the foramen caecum; it sends a series of tubular prolongations round the filaments of the olfactory nerves as they pass through the cribiform plate, and also round the nasal nerve as it passes through the nasal slit; a prolongation is also continued through the sphenoidal fissure into the orbit, and another is continued into the same cavity through the optic foramen, forming a sheath for the optic nerve, which is continued as far as the eyeball. In the posterior fossa it sends a process down the internal auditory meatus, ensheathing the facial and auditory nerves; another through the jugular foramen, forming a sheath for the structures which pass through this opening; and a third through the anterior condylod foramen. Around the margin of the foramen magnum it is closely adherent to the bone, and is continuous with the dura mater lining the spinal canal. In certain situations, as already mentioned (page 650), the fibrous layers of this membrane separate, to form sinuses for the passage of venous blood. Upon the outer surface of the dura mater, in the situation of the longitudinal sinus, may be seen numerous small whitish bodies, the glandula Pacchioni.

Structure.—The dura mater consists of white fibrous and elastic tissues arranged in flattened laminae, which are divisible into two layers, the fibres of the two layers intersecting each other obliquely. A layer of nucleated endothelial cells, similar to those found on serous membranes, lines its inner surface; these were formerly regarded as belonging to the arachnoid membrane.

Its arteries are very numerous, but are chiefly distributed to the bones. Those found in the anterior fossa are the anterior meningeal branches of the anterior and posterior ethmoidal and internal carotid, and a branch from the middle meningeal. In the middle fossa are the middle and small meningeal branches of the internal maxillary, a branch from the ascending pharyngeal, which enters the skull through the foramen lacerum medium basis crani; branches from the internal carotid, and a recurrent branch from the lachrymal. In the posterior fossa are meningeal branches from the occipital, one of which enters the skull through the jugular foramen, and the other through the mastoid foramen; the posterior meningeal, from the vertebral; occasionally meningeal branches from the ascending pharyngeal, which enter the skull, one at the jugular foramen, the other at the anterior condylod foramen, and a branch from the middle meningeal.

The veins, which return the blood from the dura mater, and partly from the bones, anastomose with the diploic veins. These vessels terminate in the various sinuses, with the exception of two which accompany the middle meningeal artery, and pass out of the skull at the foramen spinosum to join the internal maxillary vein.

The nerves of the dura mater are, the recurrent branch of the fourth and filaments from the Gasserian ganglion, from the ophthalmic and hypoglossal nerves, and from the sympathetic.

The so-called glandulae Pacchioni are numerous small whitish granulations, usually collected into clusters of variable size, which are found in the following
situations: 1. Upon the outer surface of the dura mater, in the vicinity of the superior longitudinal sinus, being received into little depressions on the inner surface of the calvarium. 2. On the inner surface of the dura mater. 3. In the superior longitudinal sinus. 4. On the pia mater, near the margin of the hemispheres.

These bodies are not glandular in structure, but simply enlarged normal villi of the arachnoid. In their growth they perforate the dura mater, and are thus found on its outer surface, and when of large size they cause absorption of the bone, and come to be lodged in pits or depressions on the inner table of the skull. The manner in which they perforate the dura mater is as follows: At an early period of their growth they project through minute holes in the inner layer of the dura mater, which open into large venous spaces situated in the tissues of the membrane on either side of the longitudinal sinus and communicating with it. In their onward growth the villi push the outer layer of the dura mater before them, and this forms over them a delicate membranous sheath. In structure they consist of trabeculae of connective tissue covered over by a layer of endothelium. The spongy tissue of which they are composed is continuous with the trabecular tissue of the subarachnoid space.

These bodies are not found in infancy, and very rarely until the third year. They are usually found after the seventh year, and from this period they increase in number as age advances. Occasionally they are wanting.

Processes of the Dura Mater.—The processes of the dura mater, sent inward into the cavity of the skull, are three in number: the falx cerebri, the tentorium cerebelli, and the falx cerebelli.

The falx cerebri, so named from its sickle-like form, is a strong arched process of the dura mater, which descends vertically in the longitudinal fissure between the two hemispheres of the brain. It is narrow in front, where it is attached to the crista galli of the ethmoid bone, and broad behind, where it is connected with the upper surface of the tentorium. Its upper margin is convex, and attached to the inner surface of the skull as far back as the internal occipital protuberance. In this situation it is broad, and contains the superior longitudinal sinus. Its lower margin is free, concave, and presents a sharp curved edge, which contains the inferior longitudinal sinus.

The tentorium cerebelli is an arched lamina of dura mater, elevated in the middle and inclining downward toward the circumference. It covers the upper surface of the cerebellum, and supports the occipital lobes of the brain, and prevents them pressing upon the cerebellum. It is attached, behind, by its convex border to the transverse ridges upon the inner surface of the occipital bone, and there encloses the lateral sinuses; in front, to the superior margin of the petrous portion of the temporal bone, enclosing the superior petrosal sinuses; and at the apex of this bone the free or internal border and the attached or external border meet, and, forming two processes, cross one another and are continued forward, to be attached to the anterior and posterior clinoid processes respectively. Along the middle line of its upper surface the posterior border of the falx cerebri is attached, the straight sinus being placed at their point of junction. Its anterior border is free and concave, and presents a large oval opening for the transmission of the crura cerebri.

The falx cerebelli is a small triangular process of dura mater received into the indentation between the two lateral lobes of the cerebellum behind. Its base is attached, above, to the under and back part of the tentorium; its posterior margin, to the lower division of the vertical crest on the inner surface of the occipital bone. As it descends it sometimes divides into two smaller folds, which are lost on the sides of the foramen magnum.

The Arachnoid Membrane.

The arachnoid (ἄραχνη ἔιδος, like a spider’s web), so named from its extreme thinness, is a delicate membrane which envelops the brain, lying between the pia
mater internally and the dura mater externally; from this latter membrane it is separated by a space, the subdural space.

It invests the brain loosely, being separated from direct contact with the cerebral substance by the pia mater, and a quantity of loose areolar tissue, the subarachnoidean. On the upper surface of the cerebrum the arachnoid is thin and transparent, and may be easily demonstrated by injecting a stream of air beneath it by means of a blowpipe; it passes over the convolutions without dipping down into the sulci between them. At the base of the brain the arachnoid is thicker, and slightly opaque toward the central part; it covers the anterior lobes, and extends across between the two tempo-sphenoidal lobes, so as to leave a considerable interval between it and the brain. the anterior subarachnoidean space; it is in contact with the pons and under surface of the cerebellum, but between the hemispheres of the cerebellum and the medulla oblongata another considerable interval is left between it and the brain, called the posterior subarachnoidean space. These two spaces communicate together across the crura cerebelli. The arachnoid membrane surrounds the nerves which arise from the brain, and encloses them in loose sheaths as far as their point of exit from the skull.

The subarachnoid space is the interval between the arachnoid and pia mater: this space is narrow on the surface of the hemispheres, but at the base of the brain a wide interval is left between the two tempo-sphenoidal lobes, and, behind, between the hemispheres of the cerebellum and the medulla oblongata. This space is the seat of an abundant serous secretion, the cerebro-spinal fluid, which fills up the interval between the arachnoid and pia mater. The subarachnoid space usually communicates with the general ventricular cavity of the brain by means of an opening in the inferior boundary of the fourth ventricle.

The subdural space also contains fluid; this is, however, small in quantity compared with the cerebro-spinal fluid.

Structure.—The arachnoid consists of bundles of white fibrous and elastic tissue intimately blended together. Its outer surface is covered with a layer of endothelium. From its inner surface are given off a number of bundles of fine connective tissue, which form a sponge-like trabecular network in the subarachnoid space, in the interstices of which the cerebro-spinal fluid is contained. Vessels of considerable size, but few in number, and, according to Bochdalek, a rich plexus of nerves derived from the motor division of the fifth, the facial, and the spinal accessory nerves, are found in the arachnoid.

The cerebro-spinal fluid fills up the subarachnoid space. It is a clear, limpid fluid, having a saltish taste and a slightly alkaline reaction. According to Lassaigne, it consists of 98.5 parts of water, the remaining 1.5 per cent. being solid matters, animal and saline. It varies in quantity, being most abundant in old persons, and is quickly reproduced. Its chief use is probably to afford mechanical protection to the nervous centres and to prevent the effects of concussions communicated from without.

The Pia Mater.

The pia mater is a vascular membrane, and derives its blood from the internal carotid and vertebral arteries. It consists of a minute plexus of blood-vessels, held together by an extremely fine areolar tissue. It invests the entire surface of the brain, dipping down between the convolutions and laminae, and is prolonged into the interior, forming the velum interpositum and choroid plexuses of the fourth ventricle. It represents only the inner layer of the pia mater of the cord. Upon the surfaces of the hemispheres, where it covers the gray matter of the convolutions, it is very vascular, and gives off from its inner surface a multitude of minute vessels, which extend perpendicularly for some distance into the cerebral substance. At the base of the brain, in the situation of the anterior and posterior perforated spaces, a number of long straight vessels are given off, which pass through the white matter to reach the gray substance in the interior. On the
cerebellum the membrane is more delicate, and the vessels from its inner surface are shorter. Upon the crura cerebri and pons Varolii its characters are altogether changed; it here presents a dense fibrous structure, marked only by slight traces of vascularity.

According to Fohmann and Arnold, this membrane contains numerous lymphatic vessels. Its nerves are derived from the sympathetic, and also from the third, fifth, sixth, facial, glosso-pharyngeal, pneumogastric, and spinal accessory. They accompany the branches of the arteries.

THE BRAIN.

[By Bern B. Gallaudet, M.D.,
Demonstrator of Anatomy, College of Physicians and Surgeons (Columbia University); Surgeon to Bellevue Hospital, New York City.]

GENERAL CONSIDERATIONS AND DIVISIONS.

The Brain, or encephalon, is that portion of the cerebro-spinal axis which is contained in the cranial cavity. It may be divided into five portions, which, from below upward, are as follows: 1. The medulla oblongata; 2. The pons Varolii and cerebellum; 3. The mid-brain; 4. The inter-brain; 5. The two hemispheres. The inter-brain and the two hemispheres are sometimes grouped together as the cerebrum. Commonly, however, the word "cerebrum" means the two hemispheres only.

These various subdivisions of the brain are based on the method of development of the brain, each of which corresponds to one of the five cerebral vesicles into which the original foetal brain, a mere tube, is soon divided.

Authorities differ as to the precise method of development of the early foetal brain after it has become a closed tube. Some observers state that this brain-tube becomes partially constricted in two places, thus giving rise to three primary cerebral vesicles, and that no further constrictions as such occur. Others claim that, while this is true, soon afterward the anterior and posterior vesicles are further subdivided by similar, though not so well-marked, constrictions.

This latter method seems, perhaps, the simpler, and is the one which will be followed in the present description.

There are thus formed, first, three primary cerebral vesicles, and then five secondary cerebral vesicles. The three former are known respectively as the fore-brain, the mid-brain, and the hind-brain. Of the five secondary vesicles, the first and second result from constriction of the fore-brain; the third is the original mid-brain unchanged, while the fourth and fifth are derived from the hind-brain in a manner similar to that in which the first two are formed from the fore-brain. The first secondary vesicle is known as the prosencephalon; the second, as the thalamencephalon; the third, as the mesencephalon, or mid-brain; the fourth, as the piencephalon; and the fifth, as the metencephalon (Fig. 412). Each of these subdivisions, of course, contains its own portion of the original brain-cavity, and these various portions are all in direct continuity, one with the other.

In comparing these divisions of the embryonal brain with those of the adult brain already mentioned, it is found that the prosencephalon, together with the thalamencephalon, develop into or go to form the inter-brain, and hence their cavities make up the third ventricle, which is the name given to that portion of the general brain-cavity, in the adult, included in the inter-brain. It is common, however, in describing the adult brain to use the names "inter-brain" and "thalamencephalon" interchangeably, thus disregarding the prosencephalon. The reason for this is that the latter, in the adult brain, is merely the extreme anterior part of the true thalamencephalon, while its cavity holds a similar relation to the third ventricle—i.e., it is only the anterior end of the ventricle. It is that portion of the third ventricle which has on each side the opening known as the foramen of Monro, the significance of which will be dwelt upon later.
The mesencephalon, or mid-brain, simply develops into the corresponding portion of the adult brain which is known by the same name, mid-brain. The epenencephalon becomes the future pons Varolii and cerebellum, while the metencephalon develops into the medulla oblongata. These names, "prosencephalon," etc., which have been given to the five secondary cerebral vesicles, are also used, sometimes, to designate the corresponding divisions of the adult brain. The terms "hind-brain" and "after-brain" are often employed, the former as a name for the pons and cerebellum, the latter for the medulla.

It will be observed that in making the above comparison there has been no mention of the hemispheres nor of a corresponding portion of the embryonal brain. This point will now be touched upon. Soon after the formation of the primary, or simultaneously with that of the secondary, cerebral vesicles there grows out from each side of the front part of the fore-brain or prosencephalon a hollow protrusion. These protrusions from the sides of the prosencephalon are known as the "hemisphere" vesicles, and each one is to form the corresponding hemisphere of the adult brain (Fig. 412). This development is brought about by a process of extension and growth in all directions, forward, backward, upward, and downward, until, as the hemispheres, the enormously enlarged hemisphere vesicles come close together above, and overlie from above downward all the remaining divisions of the encephalon. (The term "fore-brain" is sometimes used to designate the prosencephalon and the hemispheres.)

It will be remembered that the name "third ventricle" means the cavity of the inter-brain. The cavities of the other divisions are known as follows: That

---

of each of the hemispheres is the lateral ventricle of the corresponding side; that of the mid-brain is the aqueduct of Sylvius; while that of the pons and cerebellum
and of the medulla is described as one cavity under the name of the fourth ventricle. These spaces all communicate with one another (Fig. 413). Thus the fourth ventricle opens above into the aqueduct of Sylvius, which in its turn leads into the back part of the third ventricle, and this, from its front portion laterally, communicates with each lateral ventricle by means of the corresponding foramen of Monro. It is thus seen that this foramen was originally the simple orifice formed by the protrusion of the hemisphere vesicle from the side of the prosencephalon (Fig. 414).

**THE MEDULLA OBLONGATA** (Figs. 415 and 416).

**General Description.**

The medulla oblongata, or spinal bulb, is the first division of the brain, proceeding from below upward. It has two extremities, superior and inferior, and four surfaces, dorsal, ventral, and two lateral. The inferior extremity is directly connected with the spinal cord; the upper has a similarly direct connection with the pons Varolii (Fig. 415). The surfaces in the upper half of the medulla are distinct from each other; in the lower half each runs into the other by insensible gradations. Hence the outline of a cross-section of the upper half would show each of these surfaces distinctly, while a similar outline of the lower half would be almost that of a circle.

The lateral diameter of the medulla increases from below upward, that of the lower end being about equal to that of the cord, while that of the upper is but little less than that of the pons. The dorso-ventral diameter also increases slightly from below upward, but is always less, at any given level, than the corresponding lateral diameter. Hence the medulla is somewhat flattened dorso-ventrally and expands laterally as it ascends. It is directed obliquely from below upward and forward, and its lower end, which joins the cord, is on a level with the lower margin of the foramen magnum. Its ventral surface rests on the basilar groove of the occipital bone, while its dorsal surface lies under the space which separates the two hemispheres of the cerebellum. Ventrally its upper end
is clearly marked off from the pons by prominent transversely directed fibres belonging to the latter; dorsally, however, there is no such line of separation, the dorsal surface passing directly and smoothly into that of the pons. The length of the medulla is nearly 1 inch (20 to 24 mm.); its greatest lateral diameter is about three-quarters of an inch (17 to 18 mm.); its greatest dorso-ventral diameter is somewhat less (15 mm.).

The further description of the medulla will be divided into that of its surface and that of its internal structure.

Surface.

The Surfaces of the Medulla.—The ventral surface of the medulla is divided into two symmetrical lateral halves by the continuation upward of the anterior median fissure of the spinal cord. This continues up to the pons, where it terminates in a recess, the foramen caecum of Vicq d’Azyr. It is interrupted, however, for a short distance after its passage into the medulla by the decussation of the crossed pyramidal tracts of the cord. The dorsal surface of the lower half of the medulla is similarly divided by the posterior median fissure of the cord, which does not extend on to the dorsal surface of the upper half. This surface is, however, bisected by a groove or sulcus which lies in the middle line and extends from the junction of the upper and lower halves of the medulla on to the dorsal surface of the pons as far as its upper extremity.

Each lateral surface of the medulla is separated from the adjacent halves of the dorsal and ventral surfaces by a groove, well marked above, less distinct below. These grooves may be called, respectively, the dorso-lateral and ventro-lateral grooves of the medulla.

The dorso-lateral groove is the continuation upward of the postero-lateral groove of the cord, and from it emerge the fibres of the accessory portion of the spinal accessory nerve, of the vagus, of the glosso-pharyngeal, and, from the extreme upper part, close to the pons, the fibres of the seventh and mesial root of the eighth. There are two points to be noted in connection with this groove: First, it is interrupted at its lower end by the change in position of the direct cerebellar tract of the cord. In the cord this tract is anterior to the postero-lateral groove, but as it passes upward into the medulla it becomes dorsal to the groove, and thus belongs to the corresponding half of the medullary dorsal surface. Secondly, its direction is not straight up and down, but is upward, forward, and outward. The reason for this change of direction, as well as for the cessation of the posterior median fissure, will be explained below.

The ventro-lateral groove is the direct continuation upward of the line of emergence of the anterior roots of the spinal nerves, although in the cord there is no similar sulcus. Out of this groove, in the upper half of the medulla, where it is very distinct, pass the fibres of the hypoglossal nerve.

These various surfaces will now be considered in detail.

The Ventral Surface of the Medulla.—Its lower half is made up, mesially, of the decussation of the crossed pyramidal tracts, and, laterally, of the continuations upward of the direct pyramidal tracts of the cord. Hence it is undivided, and extends laterally from the lower part of one ventro-lateral groove of the medulla to the other. Its upper half is divided in two, as already stated, by the anterior median fissure. These two halves are known as the pyramids.

The pyramids are two prominent, somewhat pyramidal shaped bundles of white matter or nerve-fibres, placed one on either side of the anterior median fissure, each being separated from the upper half of the corresponding lateral surface by the upper part of the ventro-lateral groove. Superiorly, they reach to the pons, at the lower border of which they are somewhat constricted. Each, as it descends, becomes somewhat enlarged, and then tapers at its lower extremity. The fibres of which each pyramid is composed are disposed in two bundles,
a large mesial and a smaller lateral one. The fibres of the former are directly continuous with those of the crossed pyramidal tract of the opposite side of the cord by means of the decussation already referred to. This decussation is more commonly spoken of as the decussation of the pyramids. The fibres of the lateral bundle are directly continuous with those of the direct pyramidal tract of the same side of the cord. This tract, it will be remembered, in the cord is next to the anterior median fissure. Hence in the pyramid it is displaced laterally by the passage upward, next to the median fissure, of the crossed pyramidal tract after its decussation with its fellow of the opposite side. Each pyramid, close to the pons, is often crossed by a fairly-well marked band of fibres, the ponticulus of Arnold. The fibres of the pyramid are continued directly upward into the pons Varolii.

The Lateral Surface of the Medulla.—Each of these surfaces, as already stated, is separated from the corresponding half of the ventral and dorsal surface respectively by the ventro-lateral and dorso-lateral groove. The entire upper half of this surface is occupied by a well-marked olive-shaped prominence, the olive or olivary body. The lower half, below the olive, is often spoken of as the "lateral tract" of the medulla. It is not raised up from the general surface, as is the olive, and consists of white fibres derived from the antero-lateral ground bundle and antero-lateral ascending and descending cerebellar tracts of the cord. These fibres pass upward, some going beneath the olive (the major part), while others proceed over its surface, thus forming part of its structure, and still others are found in the grooves on each side of the olive. The fibres in the grooves may be considered as coming from the cerebellar tracts (ascending and descending), while those on the surface, and those which dip under or beneath the olive, are direct prolongations of the antero-lateral ground bundle. The further destination of all these fibres will be noted later on.

The Olive or Olivary Body.—This has just been partially described. It is made up of the white fibres above mentioned, and also of a nucleus of gray matter in its substance, the projection of which really causes the prominence itself, or the olive. This nucleus is the olivary nucleus or dentate nucleus of the olivary body. It will be further considered below. The upper end of the olive reaches nearly to the pons, only a short but deep, transversely directed groove intervening. This small groove really connects the upper ends of the dorso-lateral and ventro-lateral grooves, between which the olive is placed, and which are here nearer together than their lower portions, owing to the forward tendency of the former. Between the olive and pyramid (ventro-lateral groove) emerge the fibres of the hypoglossal nerve. The olive is equal in breadth to the pyramid, is a little broader above than below, and is about half an inch in length. Numerous white fibres (superficial arciform fibres) are seen winding across the lower half of the pyramid and the olivary body to enter the restiform body (see below).

The Dorsal Surface of the Medulla.—The lower half of this surface is divided in two by the posterior median fissure continued upward from the cord. Each of these halves of the lower half of the dorsal surface of the medulla is separated from the so-called lateral tract or area by the inferior portion of the dorso-lateral groove, and receives the upward prolongation of the direct cerebellar tract of the cord, as already mentioned. Situated in and forming parts of this same portion of the dorsal surface of the medulla are three other columns or tracts of white matter, besides the one just mentioned. These columns are known as funiculi, and are placed side by side, separated by slight grooves, between the direct cerebellar tract laterally and the posterior median fissure mesially. The one next to the direct cerebellar tract is the funiculus of Rolando, adjoining which is the funiculus cuneatus, and the innermost, next to the fissure, is the funiculus gracilis. The upper half of the dorsal surface of the medulla is considerably wider than the lower, this increase in width being progressive from below upward. Its
appearance is therefore somewhat like that of an equilateral triangle, base uppermost and with thick rounded sides. It is divided in two, as before stated, by a longitudinal mesial sulcus or groove. The lateral boundary of each of these halves of the upper half of the dorsal surface is the superior portion of the dorso-lateral groove, immediately beyond which is, of course, the olivary body on the lateral surface. The thick rounded sides of the "triangle" are the restiform bodies, and the space between them, including the longitudinal mesial groove, is the lower half of the floor of the fourth ventricle. The restiform bodies project dorsally, so that they are slightly elevated above this part of the floor of the fourth ventricle, which they bound.

The Funiculus Gracilis—Open and Closed Portions of the Medulla.—The funiculus gracilis is the column immediately next to the posterior median fissure on the dorsal surface of the lower half of the medulla, and its fibres are continued directly up from the postero-mesial column (column of Goll) of the spinal cord. Its upper end is slightly enlarged, and is somewhat more prominent than the rest of the column. This enlargement and prominence are due to the nucleus found in its substance at this point (Fig. 417). The term clava is given to this enlarged upper end. The two clavae diverge from each other, and each encroaches somewhat on the inner aspect of the lower part of the restiform body, thus excluding this particular part of the restiform body from its place as lateral boundary of this the lowest portion of the floor of the fourth ventricle, and becoming itself such boundary. As each clava ascends it tapers gradually to a point, and is lost on the restiform body. The course of the fibres of the gracilis and its nucleus will be described under the "internal structure" of the medulla. The fibres do not join with those of the restiform body. The angle of divergence of the clavae indicates the points of cessation of the posterior median fissure and of the beginning of the groove which lies along the middle of the floor of the fourth ventricle. In other words, it is at this spot that the lower half of the medulla, which contains the upper part of the central canal of the spinal cord, now begins to widen out and become somewhat flattened dorso-ventrally. This wide separation of its edges necessarily destroys the median fissure and brings to the surface the central canal of the cord, covered in only by the dorsal part of its lining epithelium and a delicate layer of gray matter. The canal now shares in the widening-out process and becomes the lower half of the fourth ventricle, the roof of which is the same layer of epithelium and gray matter, but which now stretches across, as a delicate triangular-shaped lamina, between the inner margins of the restiform bodies and the clavae, with its apex necessarily right in the angle of divergence of the clavae. This layer always comes away with the removal of the pia mater; hence in specimens stripped of pia there is seen, of the lower half of the fourth ventricle, only its floor and lateral boundaries. For this reason also the lower half of the medulla is often called the closed portion, and the upper half the open or ventricular portion. (See Tela choroidea inferior.)

The Funiculus Cuneatus.—This column is next to the gracilis, and the fibres of which it is composed are the direct continuations upward of the fibres of the postero-lateral column (column of Burdach) of the cord. Its upper end, lying immediately under the restiform body, is enlarged and prominent, like that of the gracilis, but to a less extent. This prominence is known as the cuneate tubercle, and is due to the projection of a nucleus within its substance (Fig. 417).

The Funiculus of Rolando.—This column is lateral to the funiculus cuneatus, and, like it, its upper end is somewhat enlarged and prominent, this prominence being known as the tubercle of Rolando. There is also a nucleus (Fig. 417) within its substance, and its upper end lies immediately beneath the restiform body. This column is found only in the medulla, it having, apparently, no corresponding column in the cord.

The Lower Half of the Floor of the Fourth Ventricle.—This is the triangular space already mentioned as lying between the restiform bodies and clavae of the funiculi graciles. Its base joins that of a similar triangular space (upper half of
the floor of the fourth ventricle) found on the dorsum of the pons. Its further consideration will be postponed until the floor as a whole is described.

The Restiform Bodies.—These are the largest and thickest "columns" found on the medulla. Each is a well-rounded mass of white fibres, and is directed from below upward, outward, and somewhat forward, diverging from its fellow. Its upper extremity is at the widest part of the medulla, where it bends, almost at a right angle, directly dorsally away from the medulla, and immediately enters the cerebellum. Hence a synonym of the restiform body is the inferior peduncle of the cerebellum. Its lower extremity is somewhat tapering, and not so rounded and prominent as are the succeeding portions. This is due to the fact that the upper ends of the gracilis, cuneatus, and Rolandic columns are not quite on the same level, the cuneatus reaching a little higher than the gracilis, and the Rolandic column a little higher than the cuneatus. The fibres of these three columns end here in a manner to be subsequently described. They do not enter the restiform body, which does receive, on the contrary, all the fibres of the direct cerebellar tract, previously mentioned. The "widening-out" of the medulla in its growth explains the divergence and oblique position of the restiform body, as well as the change in direction of the dorso-lateral groove, which separates the restiform body from the olive, and out of which emerge the fibres of origin of the seventh to the eleventh, inclusive, cranial nerves (except the lateral root of the eighth).

External Arciform Fibres.—The external arciform or arcuate fibres are seen on all three surfaces of the medulla. They are small, but vary in number in different medullae. They emerge from the anterior median fissure, between the pyramids, and curve dorsally on both sides. They pass over the pyramid and olive, and then turn upward to join the restiform body. In doing so they often conceal from view the upper part of the cuneate and Rolandic funiculi. Often these fibres are collected into a well-marked bundle which crosses inferior to the olive, thus obscuring the "lateral tract" and portions of the grooves between the pyramid, olive, and restiform body. Sometimes they spread out over the entire surface of the olivary body.

Internal Structure.

The internal structure of the medulla includes that of the whole medulla—i. e. its various surfaces, already described, as well as the deep portion surrounded and included by these surfaces.

The deep portion is divided into three bilateral areas, separated by a median raphe or septum, each of which is known respectively as the anterior, lateral, and posterior area of the medulla, and each of which corresponds to, or may be regarded as having for its superficial or "surface" aspect, one of the subdivisions of the surface of the medulla. Thus, the anterior area corresponds to one-half of the decussation of the pyramids and to the pyramid of its own side; the lateral area, to the olive and lateral tract; the posterior area, to the restiform body, floor of fourth ventricle, and the four small columns below—viz. the direct cerebellar tract, the funiculus of Rolando, cuneatus, and gracilis. These areas, observed in transverse sections, are seen to be somewhat wedge-shaped, especially in the lower half of the medulla, and each to be separated from the adjacent one by a line of nerve-fibres running dorso-ventrally through the substance of the bulb (Fig. 417). Furthermore, the two anterior areas have between them the raphe, while the two posterior, in the lower half of the medulla, are separated by the posterior median fissure. The nerve-fibres referred to above are the root-bundles of the hypoglossal nerve on the one hand, and, depending on the level of the section, of either the seventh, glossopharyngeal, vagus, or spinal accessory on the other; the root-bundles of these last being, of course, in the same perpendicular plane. These fibres are all proceeding from their various nuclei of origin in the dorsal part of the medulla, to emerge, those of the hypoglossal
between the pyramid and olive, those of the last-named group between the olive and restiform body. It is thus seen that these fibres, traced dorsally, are right in line with the corresponding groove, ventro-lateral and dorso-lateral, and the similarity between the methods of division of the "deep portion" of the medulla and its "surface" is rendered complete; thus, the root-bundles of the twelfth separate the anterior and lateral areas, while those of the seventh (some of the eighth), ninth, tenth, and eleventh, according to the level, run between the lateral and posterior areas.

Each of the above "areas" is made up of gray and white matter, the former being derived in part from that of the cord. The latter is composed of fibres, some longitudinal, directly continued up from the cord, and others running for the most part transversely, but with a slight dorso-ventral curve, and intersecting the preceding ones. Between these intersecting fibres are scattered the various cells and nuclei of gray matter which, together with their processes, form a network. This network, together with the intersection of the white fibres, gives a reticular appearance to cross-sections of the medulla, which is known as the \textit{formatio reticularis}.

As there is quite a difference between the structure and appearance of both areas and \textit{formatio reticularis} as they occur in the upper (ventricular) or lower (closed) portion of the medulla, as well as between that of the corresponding surfaces, it will be more convenient to describe the internal structure of each half of the medulla separately.

The Lower or Closed Part of the Medulla.—The \textit{gray matter} is here more directly continuous with that of the cord, the central canal of which is still present, but placed dorsally, and the posterior median fissure and decussation of the pyramids are also seen. The "widening-out" of the medulla and the decussation of the crossed pyramidal tracts of the cord are the prime factors in bringing about the following changes in arrangement of the gray matter as compared to that of the cord (see Figs. 418, 419, and 420). The \textit{anterior cornu} (in the cord) is broken up by the crossed pyramidal tract passing through it from behind forward and inward to gain the pyramid of the opposite side. The \textit{caput cornu}
is thus separated from the base, and becomes pushed over laterally. At first it is somewhat distinct, but as seen in sections immediately above (Fig. 420) it rapidly becomes disintegrated, as it were, into the gray matter of the formatio reticularis of the anterior and lateral areas (see above). The base of the cornu remains as a portion of gray matter close to the ventro-lateral aspect of the central canal. The lateral horn (Fig. 417) of the cord is also somewhat isolated, and is seen in the lateral area near the surface as the nucleus lateralis.

The posterior cornu (Figs. 418, 419, 420) is changed thus: The caput of the posterior horn becomes enlarged, and gradually shifted outward, so that it forms a rounded mass, which produces the prominence on the surface called the funiculus of Rolando and its tubercle. The neck of the cornu diminishes in size, and is broken up into a reticular formation, which blends with that derived from the anterior cornu, by the passage of longitudinal and transverse fibres through it, so that the caput is separated from the rest of the gray matter.

Just before and as the central canal expands into the fourth ventricle the base of the posterior horn of gray matter is pushed outward into the funiculus cuneatus and foniculus gracilis; in each of these funiculi it forms a distinct accumulation of gray matter, constituting the nucleus cuneatus and the nucleus gracilis. These nuclei may be regarded as helping to form the “formatio reticularis” of the posterior area, although the reticular appearance is much less marked than in the lateral or anterior area. On the surface these nuclei produce, respectively, the cuneate tubercle and clara. A small portion of the base of the posterior horn is separated from the remainder, and is placed lateral to the cuneate nucleus; it is known as the accessory cuneate nucleus, probably derived from Clarke’s vesicular column (gray matter) of the cord. Fibres from this nucleus run to the restiform body.

The white matter of the closed portion of the medulla is made up of white fibres, some collected into large bundles on the surface, while others are found in the formatio reticularis. The latter, being directly continued upward into the fibres of the formatio reticularis of the upper or open portion of the medulla, will be taken up in the description of that region.

The fibres on the surface:

Of these the decussation of the pyramids, the “lateral tract,” and direct cerebellar tract have been already dwelt upon. They will again be referred to, however, in connection with the upper part of the bulb.

The funiculus of Rolando is due to the enlarged head of the posterior cornu of the gray matter, which is displaced laterally in consequence of the increase in size of the posterior columns of the medulla, so that it lies almost at right angles
to the posterior median fissure, and approaching the surface forms a prominence which is covered over by a very thin layer of white matter derived from the funiculus cuneatus. Its most prominent part is its upper end, which is called the tuberelle of Rolando.

The funiculus cuneatus is the direct continuation upward of the posterolateral column of the cord—i.e., its white fibres are derived from this region of the cord. The fibres end in the gray matter which forms the so-called nucleus of this column: this nucleus, at first narrow, gradually enlarges, and produces, externally, the eminence mentioned above as the tuberulum cuneatum.

The funiculus gracilis is the direct continuation upward of the posterior median column of the cord. It consists entirely of white fibres, which are continuous with those of this region of the cord. Like the funiculus cuneatus, its fibres end in its so-called nucleus, which produces externally the prominence mentioned above as the clava.

The Upper, Open, or Ventricular Part of the Medulla.—The gray matter, as in the lower part, contributes to form a formatio reticularis, but this is confined chiefly to the anterior and lateral "areas." In the posterior "area" the gray matter, dorsally, is found to consist mainly of numerous individual masses of cells or nuclei scattered among fibres which are mostly longitudinal, while ventrally there is a small amount of reticular formation.

There are also other individual nuclei found in the anterior and lateral areas.

Gray Matter of the Anterior and Lateral Areas.

—This is chiefly seen in the formatio reticularis, dorsal to the pyramids and olives (Figs. 417 and 421). It is practically a continuation upward of the same structure in the closed portion of the bulb. In the anterior area the nerve-cells are infrequent and small as compared with those in the lateral area, giving a whiter appearance on section. Hence that part of the formatio reticularis which is in the anterior area is called the formatio reticularis alba, while that of the lateral area is known as the formatio reticularis grisea. Just anterior to the latter—in fact, projecting into the olive, the prominence of which it produces—is a large isolated nucleus, the nucleus of the olivary body (Figs. 417, 420, and 421). This is really a hollow capsule, with an opening or hilum directed toward the middle line. White fibres extend into and proceed out of this capsule through the hilum, constituting the so-called olivary peduncle. On section the wall of this capsule is seen to be wavy and irregular in outline; hence the nucleus is often called the corpus dentatum or dentate nucleus of the olivary body. Microscopically, the wall of the nucleus appears to be made up of neuralgia, in which are placed small multipolar nerve-cells. From the surface this nucleus is not seen, being concealed by the fibres of the olive.

In addition to the main olivary nucleus there are two accessory olivary nuclei (Fig. 417), "inner" and "outer" respectively. The former is in the anterior area, dorsal to the pyramid; the latter in the lateral area, dorsal to the main nucleus.

Gray Matter of the Posterior Area (Figs. 417, 420, and 421).— Inferiorly, close to the lower half of the bulb, are seen the upper ends of the nuclei of the funiculus cuneatus and gracilis. The bulk of this gray matter, however, is observed, on section, to consist of numerous nuclei, ventral and mesial to which is a small area of reticular formation.

The Nuclei (Fig. 417).—It must be remembered that the region now being considered is just ventral to the floor of the fourth ventricle and the restiform bodies. In other words, owing to the "widening-out" process which has occurred in this part of the medulla the posterior "area" has dorsal to it, laterally, the
restiform bodies, and mesially the lower half of the floor of the fourth ventricle. It is therefore more convenient to regard these nuclei in their relations to the floor of the fourth ventricle and the restiform body, and especially to the former, as there is practically but one nucleus in relation with the latter—viz. the following: Just ventral to the latter is the end of the gray matter of the tubercle of Rolando, showing somewhat indistinctly as a rounded mass traversed by the root-bundles of the vagus (Fig. 417).

**Nuclei in Relation to Floor of Fourth Ventricle.**—As before stated, in the closed portion of the medulla the base of the anterior cornua is found close to the central canal, on its ventro-lateral aspect. As the floor of the canal becomes the floor of the fourth ventricle in passing into the upper part of the medulla, it necessarily follows that this gray matter is shifted still more dorsally and comes to lie beneath (ventral to) the floor of the ventricle on each side of the median groove. In this gray matter is a column of large nerve-cells from which the roots of the hypoglossal nerve arise. Hence these cells are called the hypoglossal nucleus. This nucleus extends upward to the pons, and is covered dorsally by white fibres, which are known as the funiculus teres (see below, floor of fourth ventricle). In these fibres, dorsal and mesial to the hypoglossal nucleus, there is also a smaller group of cells, the nucleus of the funiculus teres, from which fibres are traceable to the vago-glossopharyngeal roots.

The remaining nuclei in this region are those of the auditory, glossopharyngeal, vagus, and spinal accessory nerves.

**The Nucleus of the Spinal Accessory Nerve.**—This group of cells begins in the closed part of the medulla, close to the base of the posterior cornu, and extends upward, lying beneath the beginning of the floor of the fourth ventricle, and lateral to the hypoglossal nucleus. Its upper extremity reaches to the eminentia cinerea (see below, floor of fourth ventricle). This is the nucleus of the accessory part of the nerve.

**Nuclei of the Vagus and Glossopharyngeal Nerves.**—These are known as principal and accessory. The principal nuclei of both these nerves are groups of cells practically in continuity upward with the nucleus of the spinal accessory nerve. These cells lie beneath (ventral to) the ala cinerea and inferior fovea in the floor of the fourth ventricle (which see), that of the ninth being above the tenth.

The accessory nuclei are the upper and lower portions respectively of a small, detached pear-shaped mass of gray matter (nucleus ambiguous) containing nerve-cells, which is found in the reticular formation of the posterior area at some distance from the floor of the ventricle, and about on a line, ventrally, with the ala cinerea. Its stalk is seen to extend mesially and dorsally, and fibres run in this, and then turn outward and forward to join the main bundles of their respective nerves. The nucleus of the funiculus teres (see above) is also an accessory nucleus of these nerves.

**Nuclei of the Auditory Nerve.**—These are two, dorsal and ventral. The dorsal nucleus lies external to the vago-glossopharyngeal nucleus and underneath the trigonum acustici, which is on the floor of the ventricle just lateral to the inferior fovea. The ventral or accessory nucleus lies between the two roots of the auditory nerve (which see), ventral and close to the restiform body; above, in the pons, it unites with the ganglion of the lateral root, which in this region is found mixed in with the fibres of this root as it passes around the restiform body.

The white matter of the upper part of the medulla is, like that of the lower, found on the surface in comparatively large bundles of fibres and, as smaller bundles or even as individual fibres, in the formatio reticularis of the various "areas" of the deep portion.

The surface fibres are those of the pyramid, the olivary body, and restiform body, together with small bundles in the ventro-lateral and dorso-lateral grooves.

The pyramid has already been described in discussing the ventral surface of the medulla. It only remains to state here that its fibres all proceed directly
upward into the pons, of which they should be considered a part, and then pass into the crus cerebri (mid-brain) and internal capsule (hemisphere) of the same side (Fig. 422).

The olivary body, due to the projection of its dentate nucleus (see above), has on its surface (or is made up of) longitudinal fibres continued up from the lateral tract immediately beneath it. The fibres of this lateral tract have already been traced upward from the cord. Some now pass upward over the surface of the olive to its upper end, where they dip into the deep portion of the medulla and join the fibres from the lateral tract, which have already passed beneath the olive

(see "lateral surface" of medulla for this and paragraphs immediately preceding and following).

Fibres in the Grooves.—Those in the dorso-lateral groove are the continuations upward of the antero-lateral ascending cerebellar tract (column of Gowers) of the cord. At the upper end of the groove they dip into the formatio reticularis, and pass at once into the dorsal part of the pons. Here they reach the corresponding superior peduncle of the cerebellum, turn backward and mesially in this, and then pass into the superior medullary velum, and are thus continued into the white matter of the worm or middle lobe of the cerebellum.

Those in the ventro-lateral groove on reaching its upper end may be considered to dip into the formatio reticularis, and then bend dorsally over the top of the olive to join the fibres of the restiform body, and thus reach the cerebellum. They are the upward prolongations of the antero-lateral descending cerebellar tract (column of Loewenthal) of the cord.

The Restiform Body.—As before stated, each of these columns is the largest tract on its own half of the medulla, and receives the fibres of the direct cerebellar tract (dorso-lateral ascending cerebellar tract—Flechsig's column), the antero-lateral descending cerebellar tract of the cord, and the external arciform fibres. It receives also other bands of fibres from the formatio reticularis of the medulla,
which will be mentioned below. Each restiform body passes into the cerebellum (see under "dorsal surface" of the medulla), and is therefore known, also, as the inferior peduncle of the cerebellum.

The white fibres of the deep portion, or formatio reticularis, will now be described.

**Fibres of formatio reticularis** in both closed and open portions of the medulla. —These fibres are described as longitudinal, transversal, and dorso-ventral. The longitudinal fibres really make up the bulk of the deep portion (all three "areas") of the medulla. Most of them come directly from the antero-lateral ground bundle of the cord, while others are derived from cells in the gray matter of the formatio reticularis itself. They are all more or less directly continued upward into the pons, and thence into the mid-brain and inter-brain. All of them have by no means been traced definitely from origin to destination. This last statement is equally true of the transverse and dorso-ventral fibres. But there are certain bundles in all these fibres which have been quite clearly made out, and these will at once be described.

**Longitudinal Fibres of the Formatio Reticularis.** —In each anterior area, just dorsal to the pyramid, is seen on section a well-marked bundle of fibres. This is the fillet, or lemniscus. Traced downward, each fillet, at about the level of the lower end of the pyramid, bends dorsally and medially, and then most of its fibres decussate across the middle line (raphe) with the corresponding fibres of the opposite fillet, and proceed to the cuneate and gracilis nuclei of the opposite side, in the cells of which they terminate. This decussation of the fillet is dorsal to and above the decussation of the pyramids. The remaining fibres of each fillet are traceable downward on the same side to—(1) the lateral tract of the medulla, and thence to the antero-lateral ground bundle of the cord; (2) a few fibres run through the trapezium of the pons to the ventral auditory nucleus of the opposite side.

**The Posterior Longitudinal Bundle.** —This is a band of fibres running upward in each anterior area dorsal to the fillet. Below, its fibres are continued directly into the "lateral tract," and thence into the antero-lateral ground bundle of the cord. Both this and the fillet are continued upward into the pons and mid-brain, where their final distribution will be described.

In the lateral area the longitudinal fibres do not appear in any well-marked bundles. Those on each side of and in front of the olive have been described. Those dorsal are merely indeterminate fibres of the formatio reticularis or belong to the internal arciform fibres (see page 719).

In the posterior area, besides the indeterminate fibres, two rather distinct bundles are to be noted. One is the funiculus solitarius, and the other the ascending root of the fifth nerve.

**The Ascending Root of the Fifth Nerve.** —This is seen on section (Fig. 417) to lie just external to the gray matter of the tubercle of Rolando and dorsal to the issuing root-bundles of the vagus. Lower down, its fibres may take origin from the cells of the tubercle of Rolando, but this is considered doubtful. Passing upward, this root enters the pons, and contributes most of the fibres of the regular sensory root of the fifth nerve (see page 722).

**The Funiculus Solitarius.** —This lies just ventral to the principal nuclei of the vagus and glossopharyngeal nerves. It is round on section, and is surrounded by gray matter. Traced downward, this bundle gradually disappears; upward, its fibres join with the roots of origin of the ninth and tenth, especially the former. It may thus be regarded somewhat as an "ascending root" of these nerves.

**Transverse and Dorso-ventral Fibres.** —The transverse fibres are found chiefly in the formatio reticularis of the upper half of the medulla. Of these the most important—or, rather, those which have been more or less definitely traced—are known as external and internal arciform fibres.

The external arciform fibres have already been described on the surface of the
THE BRAIN AND ITS MEMBRANES. 719

medulla (see page 712). They join the restiform body, and emerge from the anterior median fissure. Traced backward into the fissure, they enter the raphe, cross over the median line, still in the raphe, and then bend upward and become longitudinal, after which their course is not traceable. As these fibres emerge from between the pyramids a few fibres from each pyramid are said to join with them. As they pass across the ventro-lateral groove and olive they are joined by some of the internal arciform fibres (see below). Scattered amongst these fibres, or between them and adjacent parts of the medulla, are small masses of gray matter with nerve-cells. These masses are the nuclei of the external arciform fibres. The largest on each side is ventral to the pyramid.

The Internal or Deep Arciform Fibres.—A portion of these have already been mentioned. Traced upward, they start from the nuclei of the gracilis and cuneate columns, and then constitute the decussation of the fillet (see page 718). The remainder of the internal arciform fibres are known as the olivary peduncle (see page 715). The fibres of this peduncle decussate across the median line (through the raphe) with those of the opposite peduncle. It must be remembered that this peduncle, as a whole, is really a lamina of superimposed transversely running fibres, and not the mere bundle it appears to be on section. Traced from one side to the other, they start from the cells in the gray matter of the olivary nucleus (see page 715), and pass mesially out through the hilum. They then decussate, as above mentioned, with the opposite peduncle, and enter, through its hilum, the opposite olivary nucleus. Here they diverge as they approach the gray lamina of the nucleus, and proceed in different directions, after passing through the lamina. This “passing through” the lamina is not true for all the fibres, for some end in the nuclei, which in their turn give rise to new fibres which continue the course of the old ones. On “passing through,” then, the lamina, the most posterior fibres run backward through the lateral area and join the restiform body, and thus reach the cerebellum; the uppermost pass upward as longitudinal fibres in the formatio reticularis of the lateral area (see page 718), and have been traced on up to the cerebral hemisphere of the same side; the more anterior fibres run between the longitudinal fibres on the surface of the olive or between those in the grooves on each side of the olive, and there bend backward and join the external arciform fibres, and are continued to the restiform body and cerebellum.

The Raphe.—The raphe is situated in the middle line of the medulla, above the decussation of the pyramids. It consists of nerve-fibres intermingled with nerve-cells. The fibres have different directions which can only be seen in suitable microscopic sections; thus:

1. Some are dorso-ventral; these are continuous ventrally with the superficial arciform fibres, and dorsally with fibres from the strie acusticae.
2. Some are longitudinal; these are derived from the arciform fibres, both sets, which on entering the raphe change their direction and become longitudinal.
3. Some are oblique; these are continuous with the deep arciform fibres which pass from the raphe.

Some of the fibres of the raphe arise from the nuclei ventral to the floor of the fourth ventricle.

THE PONS VAROLII (Figs. 415, 416).

The pons Varolii is the ventral portion of the hind-brain, the dorsal portion being the cerebellum. The pons is in direct continuity below with the medulla, all the longitudinal fibres of each being directly continuous from one to the other, with the exceptions of the restiform bodies of the medulla, which go to the cerebellum (inferior peduncles), and the superior peduncles of the cerebellum, which, as will be seen, belong to the structure of the pons, after they leave or before they enter, according as they are traced, the cerebellum.

The pons is about one inch long, and somewhat more in width. Dorsally, it is about three-fourths of an inch (17–18 mm.), hence its thickness is
greater than that of the medulla. There are four surfaces to the pons—superior, inferior, ventral, and dorsal; the two latter are free. The superior and inferior surfaces are seen only on section, the former being attached, by direct continuation of fibres, to the mid-brain, while the latter is similarly attached to the medulla.

The ventral surface is markedly convex from side to side; it rests upon the grooved dorsal surface of the dorsum sellae of the body of the sphenoid bone. It presents along the middle line a longitudinal groove, wider in front than behind, which lodges the basilar artery. This surface consists entirely of a rather thick layer of well-marked transversely running fibres, extending across the median groove from side to side. The lowermost fibres slightly overlap the upper ends of the pyramids and cross over the extreme upper end of the anterior median fissure. The uppermost fibres, similarly but to a greater extent, overlap the lower part of the ventral surface of the mid-brain (crura cerebri or crustae). Hence it follows that this surface has an upper and lower curved free margin, and each somewhat rounded and distinct from the medulla on the one hand and the crura cerebri on the other, and that these margins have nothing to do with the respective attached surfaces of the pons. Furthermore, after crossing the middle line the superior fibres bend downward and the inferior upward. The middle fibres are exactly transverse; hence their extremities are overlapped by those of the other two sets. The extremities of all these sets of fibres are seen, in horizontal section, on the dorsal aspect of the pons, and they here form, together with other transverse fibres coming from the deep part of the pons, a large rounded bundle of fibres on each side, which is directed dorsally into the cerebellum, and is known as the middle peduncle of the cerebellum of the corresponding side. Owing to its prominence this surface is often called the tuber annulare.

The dorsal surface of the pons is almost flat, and, though free, is concealed from above by the cerebellum. It is divided into a mesial and two lateral portions. Each lateral portion is raised up somewhat from the mesial, and is seen to be a rather broad, flat band of white fibres. These bands are not parallel, but converge from below upward. Superiorly, the fibres of each are continued into the mid-brain; inferiorly, they pass into the cerebellum. These bands are the superior peduncles of the cerebellum. Besides being raised from the mesial portion, each of these peduncles overhangs it a little by its inner margin. Between the inner margins of these peduncles stretches a delicate layer of white matter (valve of Vieuussens) roofing over the following:

The mesial portion of the dorsal surface of the pons is the upper half of the floor of the fourth ventricle. Like the lower half (see page 711), it is triangular in shape, but its apex is upward. Its base corresponds to that of the lower or medullary half. As these two portions of the floor of the ventricle run into each other without any line of demarkation, it follows that the entire floor of the fourth ventricle is rhomboidal or diamond-shaped. The widest part of the floor is the line of union of the two bases of the triangles, and, if this line is continued ventrally, it will be found to run close along the lower free margin of the tuber annulare (ventral surface of pons). The floor, as a whole, will be described after the description of the pons is completed.

Relations of the Cerebellar Peduncles to Each Other.—If the cerebellum be removed from the pons and medulla by cutting through the three peduncles on each side close to the pons and medulla, it will be found that the cut ends are all grouped together in an area immediately external to the widest part of the floor of the ventricle. In this group the cut end of the middle is external to the cut ends of the superior and inferior peduncles, which here are in contact (see Fig. 416).

Deep Portion of the Pons.—This is comprised between the dorsal and ventral surfaces. It is made up of both longitudinal and transverse fibres and gray matter. The longitudinal and transverse fibres in each lateral half of the pons are arranged in two groups, ventral and dorsal.
The ventral longitudinal fibres are placed just dorsal to, and are concealed from below by, the transverse fibres of the ventral surface just described. They are the direct continuations of the fibres of the pyramid. Each of these pyramidal bundles soon after entering the pons breaks up into smaller bundles which are intersected by certain transverse fibres (see below). Superiorly, they are continued upward into the crusta of the mid-brain. These fibres lie on each side of the middle line, and cause a corresponding bulging of the tuber annulare. Thus is produced the median groove (sulcus basilaris) for the basilar artery. As they pass upward through the pons these fibres are somewhat increased in number from being reinforced by fibres derived from the nerve-cells in the ventral transverse fibres (see below).

The dorsal longitudinal fibres are separated by quite an interval from the preceding. This interval is filled in by transverse fibres, especially the trapezium (see below). They are continued upward from the formatio reticularis of the medulla, and among them are especially to be noted the ascending root of the fifth nerve, the fillet, and the posterior longitudinal bundle.

The Transverse Fibres.—These comprise ventral and dorsal, and must not be confounded, especially the former, with the superficial transverse fibres of the ventral surface (tuber annulare), already described. These transverse fibres now under discussion belong to the "deep portion" of the pons, dorsal to those of the ventral surface.

The ventral transverse fibres of the deep portion of the pons intersect the bundles of the pyramidal fibres (see above), and then curve dorsally and join with those of the ventral surface to make up the middle peduncle of the cerebellum. These transverse fibres, taken together, form a much thicker layer than the superficial set, and contain much gray matter between them. Across the median line, intersecting or dorsal to the pyramidal bundle, they meet and interlace with those coming from the opposite side. Furthermore, all of these fibres do not join the middle peduncle, many of them joining the nerve-cells, which are situated in the gray matter (nuclei pontis) of this layer. From these cells other fibres are given off which proceed to the pyramidal bundles (see above).

The dorsal transverse fibres of the deep portion of the pons, especially in its lower half, are collected into a distinct mass called, from its shape, the trapezium.

The trapezium is situated just dorsal to the pyramidal bundles, and its fibres proceed laterally on each side, tapering as they go, until they reach the cells (with which they become connected) of the accessory (ventral) auditory nucleus (Fig. 488), and, through this, the lateral root of the auditory nerve. Some of the fibres of the trapezium are connected with the cells of the superior olivary nucleus (see below), which lies just dorsally on each side, and others pass to the fillet.

The Septum or Raphe.—This is the upward prolongation of the medullary raphe. It is found in that portion of the pons which is dorsal to the trapezium, and does not extend to the ventral surface except at the upper and lower extremities of the pons. At these places certain of the raphe fibres pass out of the median line, and then bend laterally to join with and become part of the upper and lower margins, respectively, of the tuber annulare. It follows, therefore (see page 720), that some of the fibres of the upper margin of the tuber annulare actually encircle the corresponding crus cerebri.

The Gray Matter of the Pons.—This may be arranged as follows:

(a) The nuclei pontis, which are small masses of gray matter, containing small multipolar nerve-cells, found scattered between the bundles of the ventral transverse fibres (see above), and also to a less extent, between those of the tuber annulare. Some of the fibres of the latter may have an arrangement—i. e. interlacing and taking origin from these nuclei—similar to that already described as occurring in many of the fibres of the ventral transverse set.

(b) Gray Matter of the Formatio Reticularis.—This formatio, as before stated, lies dorsal to the trapezium. Its gray matter comprises, first, its own gray matter—i. e. small reticularly arranged masses with nerve-cells, exactly similar to
those of the formatio reticularis of the medulla. Secondly, and more important, a group, in each lateral half, of much more distinct nuclei, some of which are close under the floor, upper half, of the fourth ventricle, while others are more deeply, as well as laterally, situated. These distinct nuclei merit, each, a separate description, as follows:

The Superior Olivary Nucleus.—This is a mass of small nerve-cells situated just dorsal to the lateral part of the trapezium, and between the issuing root-bundles of the sixth and seventh cranial nerves. Its structure is similar to that of the inferior olivary nucleus of the medulla, though it has not the capsular form of the latter (see p. 715). Its cells give origin to some of the fibres of the trapezium (see p. 721), and these fibres, crossing the median line, pass to the accessory auditory nucleus of the opposite side (see p. 721).

The remaining “distinct” nuclei are those of various cranial nerves: One of these forms the nucleus of the sensory root of the fifth nerve; a second, the nucleus of the motor part of the same nerve; a third, the nucleus of the sixth nerve; and a fourth, the nucleus of the facial nerve. The nuclei of the auditory nerve are also prolonged upward into the pons.

Nuclei of the Auditory Nerve.—The dorsal nucleus (see p. 716) is prolonged upward into the pons, beneath the upper half of the floor of the ventricle, where it is shifted laterally and soon tapers away. It is widest at the junction between the pons and medulla. The ventral or accessory nucleus lies entirely external to the floor of the ventricle, and rather deeply in the formatio reticularis of the pons. Extremely dorsal to it is the upper end of the corresponding inferior peduncle (restiform body) of the cerebellum. It is the united accessory auditory nucleus of the medulla and nucleus of the lateral auditory root (see p. 716).

Nucleus of the Facial Nerve.—The nucleus of the seventh or facial nerve lies deeply in the substance of the formatio reticularis of the pons just dorsal to the superior olivary nucleus. The fibres of origin of the facial nerve proceed from this nucleus dorsally and mesially until they are close under the floor of the ventricle, where they are collected, on each side, into a rounded bundle. This bundle now runs upward (ascending part of the root) for a short distance close to the median line, having beneath it the nucleus of the sixth, and then makes a sharp bend, ventro-laterally, and continues its course in this direction through the substance of the pons, to emerge close under the inferior margin of the tuber annulare in the extreme upper end of the dorso-lateral medullary groove.

Nucleus of the Sixth Nerve.—This is situated immediately ventral to the upper half of the funiculus teres in the floor of the ventricle. It is external to and beneath the ascending root of the seventh, just described. The fibres of origin of the sixth nerve proceed from this nucleus obliquely ventrally and downward and through the pons, and emerge at the lower margin of the tuber annulare at a point corresponding to the upper end of the ventro-lateral medullary groove close to the pyramid.

Nuclei of the Fifth Nerve.—The motor nucleus is higher up in the pons than the nucleus of the seventh nerve, but is about on the same line. It is, furthermore, nearer the surface of the floor of the ventricle, being just ventral to the lateral margin of the latter. The sensory nucleus is larger than the motor and lies to its outer side. It would therefore lie beneath the superior peduncle of the cerebellum, and be outside of the limits of the floor of the ventricle. The cells of this nucleus are, however, smaller than those of the motor. Special fibres are seen to pass from each of these nuclei to the raphe of the pons, but the regular fibres are those of the root-bundles of the motor and sensory roots, respectively, of the fifth nerve. These root-bundles proceed ventrally and somewhat laterally through the substance of the pons, and emerge on the surface of the tuber annulare, nearer its superior than its inferior margin, and having between them some of its transverse fibres. All the fibres of each of these roots do not come, however, from its respective nucleus, for, if traced inward or dorsally, each root is seen to divide, just before reaching its nucleus, into two bundles, the
smaller of which, in each case, goes to the *nucleus*, while the other takes a distinct course, differing for the two roots, thus: The "non-nuclear" division of the motor root passes upward as a distinct bundle through the dorsal part of the pons and into the mid-brain, where its fibres terminate in a group of large nerve-cells situated in the gray matter on the side of the *aqueduct of Sylvius*. This is the so-called *descending root* of the fifth nerve. The "non-nuclear" division of the sensory root is the so-called *ascending root* of the fifth nerve, already sufficiently described.

**Floor of the Fourth Ventricle** (Fig. 423).

As already stated, the *floor of the fourth ventricle* is made up of the *mesial portions* of the dorsal surfaces of, the pons Varolii above and *upper half* of the medulla oblongata below. It is lozenge- or diamond-shaped; that is to say, it is composed of two triangles, with their bases opposed to each other. Hence it is often called the *fossa rhomboidalis*.

The lower triangle is formed by the divergence of the clavae of the funiculi graciles and the restiform bodies. These columns pass upward and outward at an acute angle, leaving by their divergence a triangular space which forms the lower half of the floor of the fourth ventricle. In like manner the upper triangle is formed by the divergence of the superior peduncles of the cerebellum. These, traced downward, as they emerge from beneath the corpora quadrigemina of the mid-brain, are almost in contact by their inner margins, but they gradually diverge, passing downward, backward, and outward, to reach the cerebellum, thus enclosing a triangular space which forms the upper half of the floor of the fourth ventricle.

The floor presents *four angles*. The *upper angle* reaches as high as the upper border of the pons; it presents the lower opening of the *aqueduct of Sylvius*, by which this ventricle communicates with the third ventricle. The *lower angle* is the angle of divergence of the clava, and is about on a level with the lower end of the olivary body. It presents a minute opening, the aperture of the central canal of the spinal cord.

The two *lateral angles* are situated each at an end of the conjoined bases of the triangles. The distance between them is the widest part of the floor. Each lateral angle is also the point of the "coming together" of the superior and inferior peduncle (restiform body) just as they pass into the cerebellum.

In the median line of the floor is a *longitudinal groove* which extends between

---

**Fig. 423.**—Floor of the fourth ventricle. (Henle.)
the upper and lower angles. From the fancied resemblance in the combined lower end of this groove and lower angle, to the nib of a writing pen, this lower angle has been named the calamus scriptorius.

On each side of the median fissure are two spindle-shaped longitudinal eminences, the fasciculi or funiculi teretes; they extend the entire length of the floor. Each eminence consists of white fibres, and is due to a portion of the base of the anterior cornu of gray matter of the cord which comes to the surface of the floor of the fourth ventricle after the central canal of the spinal cord has opened out into this cavity. This gray matter of the "base of the anterior cornu" now constitutes the nuclei of origin of the hypoglossal and sixth cranial nerves. The white fibres of the funiculus teres are partially those of the "ascending part" of the root of the seventh nerve (see page 722) and those of the formation reticularis of the posterior "area" of the medulla.

The widest part of the floor of the ventricle is crossed by several white transverse lines, lineae transversae, auditory striae, or striae acusticae; they emerge from the posterior median fissure, and, passing over the funiculi teres of the same side, some of the fibres enter the lateral root of origin of the auditory nerve, while others may be traced to the flocculus of the cerebellum. Ventrally, through the posterior median fissure, these fibres are traceable to the raphe.

Below these striae, on each side, and external to the funiculus teres, is a little fossa, called the fovea inferior; while above, similarly placed, is a fossa, called the fovea superior. Extending upward to the top of the ventricle from each superior fovea is a shallow groove; this groove is called the locus coeruleus, which presents a bluish tint through the thin stratum covering it. This tint is due to an underlying stratum of pigmented nerve-cells (substantia ferruginea). The locus coeruleus lies along the extreme lateral limit of the upper half of the floor of the ventricle, and hence converges upward toward its fellow of the opposite side. It is slightly overhung by the inner margin of the cerebellar superior peduncle. Just ventral to the locus coeruleus in the substance of the pons is the motor nucleus of the fifth nerve (see page 722).

The fovea inferior is the depressed apex, which is directed upward, of a triangular area. The floor of this triangular area is darker in color than the rest of the floor of the ventricle; hence it is called the ala cinerea. The base, being elevated in consequence of the depression of the apex, is known as the eminentia cinerea. The triangular area itself, as a whole, including inferior fovea (apex), ala cinerea (floor), and eminentia cinerea (base), is known as the trigonum vagi. Immediately ventral to this trigonum is the nucleus of origin of the vagus, and at the apex is that of the glossopharyngeal nerve.

Between the trigonum vagi and the mesial groove is the lower half of the funiculus teres. This is triangular in shape, its base turned upward toward the striae acusticae. This lower half of the funiculus teres is the trigonum hypoglossi. Ventral to it is the nucleus of origin of the hypoglossal nerve.

Between the trigonum vagi and the restiform body is another triangular area, whose base is also directed upward, and across which the striae acusticae pass. This area is the trigonum acustici. On its base is a slight eminence, the tuberculum acusticium. Ventral to this trigonum and tubercle is the dorsal nucleus of the auditory nerve.

Between the superior fovea (above the striae acusticae) and the middle groove is the upper half of the funiculus teres. Just ventral to this, but not close to the middle line, is the nucleus of origin of the sixth nerve, while the superior fovea itself may be taken as indicating the position of the nucleus of the seventh nerve, which, however, is quite deeply situated in the pons (see page 722).

THE CEREBELLUM.

The cerebellum, together with the pons Varolii, forms the hind-brain. It is, morphologically, the enormously thickened and hypertrophied middle portion of the brain-matter forming the roof of that part of the brain-cavity known as the
fourth ventricle (Fig. 424), of which the ventral boundaries are, as already described, parts of the dorsal surfaces of the pons and medulla (after-brain).

The cerebellum is contained in the inferior occipital fossae. It is situated beneath the occipital lobes of the cerebrum, from which it is separated by the tentorium. In form the cerebellum is oblong, and flattened from above downward, its great diameter being from side to side. It measures from three and a half to four inches (10 centimetres) transversely, and from two to two and a half inches from before backward, being about two inches thick in the centre and about six lines at the circumference, which is the thinnest part. It consists of gray and white matter: the former, darker than that of the cerebrum, occupies the surface; the latter, the interior. The surface of the cerebellum is not convoluted like the cerebrum, but traversed by numerous curved furrows or sulci, which vary in depth at different parts, and separate the laminae of which its exterior is composed.

Weight of the Cerebellum.—Its average weight in the male is 5 ozs. 4 drs. It attains its maximum weight between the twenty-fifth and fortieth year, its increase in weight after the fourteenth year being relatively greater in the female than in the male. The proportion between the cerebellum and cerebrum is, in the male, as 1 to 8½, and in the female, as 1 to 8½. In the infant the cerebellum is proportionately much smaller than in the adult, the relation between it and the cerebrum being, according to Chaussier, between 1 to 13 and 1 to 26; by Cruveilhier the proportion was found to be 1 to 20.

Main Lobes of the Cerebellum.—The cerebellum is divided into three large lobes, a middle and two lateral. The middle lobe is the worm, and the two lateral are the hemispheres. These lobes are not separable from each other, being joined together by their sides. Hence the upper surface of the cerebellum, as a whole,
tinct than the upper surface, and has on each side of it, marking it off from the hemisphere, a deep groove which runs antero-posteriorly. The inferior surface of the worm can be seen as a whole only after removal of the pons and medulla. The space or fossa between the inferior surfaces of the hemispheres, and which contains the inferior worm, is called the vallecula, and the grooves above mentioned, one on each side of the lower surface of the worm, are known as the sulci valleculae. The upper or anterior part of the vallecula lies dorsal to the medulla, and is continued upward into the anterior cerebellar notch; the lower or posterior part contains the lower portion of the falx cerebelli, and is continued into the posterior cerebellar notch (see below).

Although in the adult human brain each hemisphere is much larger than the worm, still the latter is morphologically the more important, being the part first developed in mammals, and, in many of them lower than man, constituting a large median lobe quite distinct from the hemispheres. Furthermore, in fishes and reptiles it is the only part which exists, the hemispheres being additions and attaining their maximum size in man.

The Notches of the Cerebellum.—The hemispheres are separated in front in the middle line by a deep notch, the anterior cerebellar notch (incisura cerebelli anterior), and also behind (similarly) by a smaller notch, posterior cerebellar notch (incisura cerebelli posterior) (Fig. 427). The anterior notch is much wider, and
its sides are much more curved, than those of the posterior. This notch is really the deeply hollowed-out "anterior margin" of the cerebellum. It lies close to the pons and upper part of the medulla, while the upper edge of the notch extends to or encircles the posterior pair of corpora quadrigemina of the mid-brain. This edge can be raised, however, and then can be seen the superior cerebellar peduncles and valve of Vieussens (see below). The posterior notch is free. When within the cranium it contains the upper part of the falx cerebelli. The sides of each notch are formed by the respective hemispheres, while the bottom of each notch, or its centre, is the anterior and posterior extremity, respectively, of the worm.

The fissures of the cerebellum are very numerous and dip deeply into its substance. Of these the largest and deepest is the great horizontal fissure. This passes completely around the cerebellum, forming its circumference as it were, and its plane is horizontal. As it crosses the median line, in front and behind, it cuts into the respective extremities of the worm, and splits the sides of each of the notches as well (see above). Hence this fissure divides each hemisphere and the worm (the entire cerebellum) into an upper and a lower half. The edges and sides of this fissure are everywhere in contact, and lined by gray matter, except where it runs across the anterior cerebellar notch, where its edges, upper and lower, are separated by the passage between them of the white matter of the worm.

All the remaining fissures of the cerebellum are lined by gray matter; their edges are everywhere in contact, and they all terminate, by one extremity at least, in the great horizontal fissure (see below for further details of these fissures).

The Worm.—This, as already stated, is the middle lobe of the cerebellum. It has an upper and a lower surface, and two extremities, anterior and posterior. The upper surface is called either the superior vermiform process or the upper worm; and the lower surface, either the inferior vermiform process or the lower worm. Its sides are attached directly to the mesial sides of the hemispheres, and are not seen except on section. Each extremity is divided by that portion of the great horizontal fissure which dips into the corresponding notch into an upper and a lower half. Hence each of these anterior halves is the anterior extremity, respectively, of the upper and lower worm; and each posterior half is, similarly, the posterior extremity of the corresponding worm. The horizontal fissure does not dip into the extremities of the worm nearly so deeply as it does into the margin of the hemispheres.

Each surface of the worm, or the upper and lower worm respectively, is subdivided into lobules by transversely directed fissures which are continued laterally into and across the corresponding surfaces of the hemisphere to the margin, where they terminate in the great horizontal fissure. Hence any two of these fissures contain between them a lobule of the upper or lower worm in the middle, and, laterally, a portion of the corresponding surfaces of the hemispheres. These fissures are known as interlobular fissures.

The Hemispheres.—Each hemisphere has a side, an upper surface, a lower surface, and a margin. The side of each is directly attached to the corresponding side of the worm. The margin is curved and extends around from the side of the posterior extremity of the worm to the corresponding side of the anterior extremity of the worm. Hence in the notches this margin is the same thing as the side of the notch. The margins of both hemispheres, together with both extremities of the worm, contain the great horizontal fissure—i.e. the upper edge of the fissure is made up of the anterior extremity of the upper worm, the margin of the upper half of one hemisphere, the posterior extremity of the upper worm, the margin of the upper half of the other hemisphere. The lower edge of the fissure is similarly made up.

The surfaces, both lower and upper, are, like those of the worm, subdivided into lobules by the lateral prolongations of the interlobular fissures, already mentioned. On the upper surface of each hemisphere these fissures are disposed
quite regularly and with a direction, somewhat curved, concavity forward, which is outward and forward. On the lower surface the interlobular fissures have not such a regular arrangement, but are much more curved, concavity forward, the curves being greater in those placed anteriorly.

The general outline of each surface has already been mentioned.

**Upper Surface of Worm and Hemispheres.**—Each of these, as already stated, is subdivided into lobules by the interlobular fissures. There are five lobules and four fissures on the upper surfaces of the worm and hemispheres, which, from before backward, are as follows (Fig. 425):

- **Lobules of superior worm**: lingula, lobulus centralis, culmen, clivus, folium cacuminis; lobules of hemisphere (upper surface): frenulum, ala, anterior crescentic lobule, posterior crescentic lobule, postero-superior lobule.

The interlobular fissures are the precentral, the post-central, the preclival, and the post-clival.

The complete arrangement is as follows: On each side of the lingula is the frenulum; these three lobules are separated by the precentral fissure from the lobulus centralis with its ala on each side. These three are in turn separated by the post-central fissure from the culmen, with the anterior crescentic lobule on each side. Posteriorly to these is the preclival fissure, behind which are the clivus and two posterior crescentic lobules, which are separated by the post-clival fissure from the folium cacuminis and postero-superior lobules, and these last are limited below by the great horizontal fissure.

**Lower Surface of Worm and Hemispheres.**—The lobules of each of these surfaces are four in number, separated by three fissures (Fig. 426). They are, from behind forward, as follows:

- **Lobules of inferior worm**: tuber valvulae, pyramid, uvula, nodulus; lobules of hemisphere (lower surface): postero-inferior lobule, digastric lobule, amygdala or tonsil, flocculus.

The interlobular fissures are the post-nodular, the prepyramidal, and the post-pyramidal.

The complete arrangement is as follows: The post-nodular fissure separates the nodulus and the two flocculi in front from the uvula and two amygdala behind; the prepyramidal fissure lies between the three last-mentioned lobules, and the pyramid with a digastric lobule on each side, which in their turn are separated by the post-pyramidal fissure from the tuber valvulae and postero-inferior lobules, while between these last and the folium cacuminis and postero-superior lobules of the upper surface runs the great horizontal fissure, which, in front, also runs between the lingula and nodulus and their prolongations.

**Lobules of the Cerebellum.**—As above mentioned, each group of three lobules (central of the worm, lateral of the hemispheres) is limited either by two interlobular fissures or by one such fissure and a portion of the great horizontal fissure. Besides these there are other smaller fissures, known as intralobular, which also run more or less transversely and cut up each lobule into still smaller subdivisions or laminae, and which are quite irregularly disposed, especially in the hemisphere lobules, where they may run obliquely, and, many of them, stop short of the margin. Furthermore, the lobules vary greatly in size and, on the under surface, in symmetry.

The structure of each lobule (Fig. 428) is seen, on an antero-posterior section, to consist of white matter surrounded by an irregular margin of gray matter, these irregularities or indentations being due to the intralobular fissures; while the interlobular fissures are seen to be deep clefts separating the lobules. Hence the cut surface of each lobule, whether of worm or hemisphere, looks like a dentated leaf or folium, the branching stems of which are white matter, and the margins gray matter; which last is also continued from lobule to lobule at the bottom of each fissure (see also page 734).

On the other hand, should the cerebellum be sliced from side to side, the plane of each transverse section corresponding as nearly as possible to that of each inter-
lobular fissure, it would appear that each group of three lobules would really constitute a single lamina, or sheet, of white matter reaching from margin to margin of the cerebellum, the central part (worm) being more prominent than the lateral portions (hemispheres); while from each surface of this lamina would appear projecting ridges also of white matter, the entire lamina and ridges being covered by gray matter. The spaces between the ridges would be, of course, the intralobular fissures.

The Lingula and Frenula.—The lingula is the smallest lobule of the upper worm (Figs. 428, 429, 430). It is peculiar from all the other lobules in that its cut surface is not like a folium, but appears merely as a series of three or four small elevations on the dorsal surface of a layer of white matter (value of Vieussens), which is here emerging from the middle part of the great horizontal fissure at the bottom of the anterior cerebellar notch. These elevations are white matter (derived directly from the valve of Vieussens) covered by a layer of gray matter which dips in between them. Posteriorly, this gray matter is continuous with that of the central lobule; anteriorly, it disappears or is continued merely as an epithelial layer over the dorsal surface of the valve of Vieussens.

The frenula (Fig. 430) stretch laterally from each side of the lingula. They are short, not reaching beyond the superior peduncles of the cerebellum, over which they lie. Each frenulum is overlapped considerably by the ala.

Lobulus Centralis and Alae (Figs. 428, 429).—The central lobule, though of good size, is much smaller than the culmen, immediately behind, and by which it is overlapped. It, in its turn, overlaps the lingula, and together with it forms the bottom of the anterior notch.

The alae are slender, and are prolonged almost to the lateral limits of the anterior notch. Hence each is curved, with the concavity forward.

Of the remaining lobules of the upper surface it may be noted that the culmen
and clivus or declive are each very large as compared to the other divisions of the upper worm (Figs. 425, 428, 429). Taken together, they constitute the bulk of the upper worm, and are the only parts seen in the natural position, for the culmen must be lifted anteriorly to show the central lobule, and the clivus posteriorly.

![Diagram](image)

**Fig. 430.**—Anterior part of cerebellum from above. The central lobule and alae are drawn backward to disclose lingula. (Henle.)

to show the folium cacuminis. On antero-posterior section each appears as made up of a number of secondary folia with well-marked intralobular fissures. The term monticulus is often applied to the combined culmen and clivus. The crescentic lobules, anterior and posterior, or lunate lobules, are large and have numerous intralobular fissures. Taken together, on each side they constitute the so-called quadrate or quadrangular or square lobule. The anterior crescentic overlaps the ala and reaches to beyond the lateral limits of the anterior notch. The folium cacuminis (see also Fig. 431) is smaller than any of the lobules of the upper worm except the lingula. Its cut surface looks like a single leaf or folium. Its lateral prolongations, however, the postero-superior lobules (superior semilunar), are large, each being fully as large, and beset with as many intralobular fissures, as either of the crescentic lobules.

**Tuber Valvulae and Postero-inferior Lobules (Fig. 431).**—The tuber valvulae is the posterior extremity of the inferior worm. It is decidedly larger than the folium cacuminis, and its cut surface shows at least one secondary folium in addition to that of its own cut surface. Its point of junction, on each side, with the postero-inferior lobule is slightly grooved. This groove is the posterior extremity.
of the corresponding sulcus valleculae (see above), which deepens as it runs forward along the side of the inferior worm. The postero-inferior lobule is as large, taken as a whole, as the larger lobules of the upper surface of the hemisphere. It resembles them also in general appearance, except that it is much more convex and its intralobular fissures are very large. These fissures are also considerably more curved, concavity forward, than those of the upper surface. Two of them are of especial depth; hence the postero-inferior lobule is often described as being made up of three subdivisions, the most posterior being called the inferior semilunar lobule; the middle one, the posterior slender lobule; and the anterior, the anterior slender lobule (lobuli gracilis). In examining the mesial extremities of these "sublobules" it is found that only that of the inferior semilunar actually joins with the tuber valvulae, while those of the other two terminate abruptly in the sulcus valleculae, and do not join with any lobule of the inferior worm.

Therefore the post-pyramidal fissure (see above) is prolonged, on the hemisphere, in front of the anterior slender lobule.

Pyramid and Digastric Lobules (Figs. 432, 433; also preceding ones).—The pyramid is a large laminated, somewhat conical projection. Its cut surface shows numerous intralobular fissures. On each side of it is the sulcus valleculae, here quite deep, and it is connected, across this sulcus, with the digastric lobule by means of a narrow connecting ridge of gray matter.

The digastric (biventral) lobule (see also Fig. 434) is triangular in general out-
line, with the apex at the "connecting ridge" just mentioned. Its laminae or subdivisions, due to its intralobar fissures, are curved, concavity forward and inward, but short, and tend more antero-posteriorly; hence the lobule is embraced posteriorly by the anterior slender lobe and post-pyramidal fissure, both of which are decidedly concave, while the laminae of the former are much longer than those of the digastic lobule. The base is anterior, and is on a line with the anterio extremity of the amygdala, and is separated from the flocculus, just in front, by the prolongation of the post-nodular fissure. Mesially the digastic lobule is separated from the amygdala by the prepyramidal fissure, which on the hemisphere runs almost antero-posteriorly, while on the inferior worm it is transverse.

**Uvula and Amygdala** (Fig. 434 and those preceding).—The uvula is longer than the pyramid. It is more prominent posteriorly than anteriorly. It has three or four well-marked transversely running intralobar fissures, clearly seen on antero-posterior section. It is connected with the amygdala on each side by means of a corrugated ridge of gray matter, the furrowed band, which lies in the sulcus valleculae. The amygdala or tonsil is a rounded mass smaller than the digastic lobule. It has a large number of intralobar fissures and laminae. These last are short and directed sagittally. Externally is the prepyramidal fissure, between it and the digastic. On removal of the amygdala a marked hollow (Fig. 433) is seen on the mesial side of the digastic. This hollow is the nidus avis (bird's nest). Internally, the amygdala is connected to the uvula by the furrowed band, and besides has a free surface bounded by the sulcus valleculae. In the natural position this surface is applied closely to the side of the uvula, which, together with that of the opposite tonsil, it conceals from view. Anteriorly is the post-nodular fissure.

**Nodulus and Flocculi** (Figs. 426-434).—The nodule is the most anterior as well as the smallest lobule of the lower worm. Its cut surface shows a single folium indented by a few intralobar fissures. It is larger than the lingula. Its white matter is usually a single stem, which branches peripherally. This stem, furthermore, like the small projections of white matter in the lingula (see page 729), which are derived from the valve of Vieussens, is seen in its turn to come from a similar, but more curved, lamina of white matter which lies at first ventral and anterior to the nodule, and then dorsally or over it. This lamina is the inferior medullary velum (see below). The sulcus valleculae on each side of the nodule is deep and wider than it is posteriorly.

The post-nodular fissure, transverse between nodule and uvula, becomes irregularly curved on the hemisphere. On leaving the worm it is at first concave forward in the sulcus valleculae, then bends, convexity forward, around the front of the amygdala and runs laterally, between the base of the digastic lobe behind and the flocculus in front, to terminate in the great horizontal fissure. In its course it receives the anterior end of the prepyramidal fissure, and at its termination in the horizontal fissure is joined by the anterior end of the post-pyram-
idal fissure. As it lies in the sulus valleculae it separates the furrowed band from a very slender lamina of gray matter which is continuous with the gray matter of the nodule mesially, and, laterally, follows the course of the post-nodular fissure until it reaches the flocculus, with the gray matter of which it is continuous. This slender lamina is known as the peduncle of the flocculus.

The flocculus is the smallest of the lobules of the inferior surface of the hemisphere, and is situated farther away from its corresponding lobule of the inferior worm than any of the others. It is a rounded, tuft-like body, its expanded extremity looking forward, and it tapers toward its peduncle. It is situated below the middle peduncle of the cerebellum; its surface is composed of gray matter, subdivided into a few small laminae; it is sometimes called the pneumogastric lobule, from being situated behind the pneumogastric nerve.

It is thus seen that the flocculus, amygdala, and digastric lobule differ in regularity, both of outline and position, from all the other lobules of the hemisphere; also that the prepyramidal fissure differs from the other interlobular fissures in that it, as a whole, is almost "horseshoe" in shape, while they have a generally transverse direction.

White Matter of the Cerebellum.—Traced from within the cerebellum, all the white matter is found to emerge from between the edges of the great horizontal fissure, where that fissure lies in the anterior cerebellar notch (Figs. 432, 433, 434). It may be described (after removal of pons and medulla by cutting close to the cerebellum) as consisting of two layers, an upper and a lower. In other words, this white matter on emerging from the cerebellum may be said to split into two diverging layers. The cleft-like space between these two layers extends entirely across the anterior cerebellar notch, at the lateral extremities of which the two layers are continuous. It has already been noted (see page 727), that the edges of the great horizontal fissure, in close contact everywhere else, are separated in the anterior notch. Hence the space between the layers might be regarded as a part of the horizontal fissure lined with white matter. Of these two layers, the upper is much the thicker and more substantial, the lower being merely a thin, delicate white lamina.

The upper layer is divisible into a mesial and two lateral portions, of which the mesial is much thinner than the lateral. This mesial portion is the valve of Vieussens or superior medullary velum. It is of uniform thickness from side to side. On transverse section, close to the cerebellum, its width is seen to be about equal to that of the upper worm. It has above it the lingula, together with the central lobule resting on the lingula. The lateral portions increase in thickness from within outward, so that the cut surface of each looks somewhat racket-shaped. Each lateral portion occupies the side of the anterior notch, and is made up of the three peduncles of the cerebellum, the handle of the racket-shaped surface representing the superior peduncle, while the rounded, expanded head represents, externally, the middle, and, inferiorly and mesially, the inferior, peduncle.

The lower layer is the inferior medullary velum. It is an exceedingly delicate white lamina, stretching from the white matter of one flocculus across the middle line to the white matter of the other flocculus. These different subdivisions will now be considered in detail.

Peduncles of the Cerebellum (Figs. 426, 432, 433).—The superior peduncles (Fig. 430) are on the dorsal surface of the pons Varolii, as previously described, diverging from each other from above downward. Each enters the corresponding hemisphere of the cerebellum beneath the frena trium and ala (Fig. 430), where its fibres blend with those of the two other peduncles and a part of the inferior medullary velum, to form the white matter of the hemisphere. The superior peduncles form the lateral boundaries of the upper part of the fourth ventricle.

The middle peduncles are large rounded bundles made up of most of the transverse fibres of the pons, as already described. Each, bending dorsally from the pons, enters the cerebellum between the edges of the horizontal fissure at the lateral limits of the anterior notch—i.e. between the ala and the edge of anterior
erescentic lobule above and flocculus below—and its fibres contribute to form part of the white matter of the hemisphere.

The inferior peduncle, restiform body of medulla, as it enters the cerebellum lies a little deeper in the anterior notch than, and inferior to, the middle peduncle. Within the cerebellum its fibres blend with those of the preceding to form the white matter of the hemisphere. Just as this peduncle bends sharply backward from the medulla, and just before it actually enters the hemisphere, its under surface is free, and forms, in this situation, the upper boundary of the cleft, above referred to, between the layers of the white matter of the cerebellum. The lower boundary of this part of the cleft is the lateral part of the inferior medullary velum.

**Inferior Medullary Velum** (Figs. 426, 429, 432, 433).—As already mentioned, this is the lower layer of the white matter of the cerebellum, and is very thin. Its central portion enters the cerebellum over or dorsal to the nodulus at the centre of the anterior notch; and at the bottom of this part of the great horizontal fissure it joins with the superior medullary velum to enter the cerebellum as the white matter of the worm. As it passes over the nodulus it is adherent to it—i.e. it sends into the nodule a stem of white matter.

As the velum passes laterally it has a curved direction, concavity forward, and extends almost to the limits of the anterior notch, where it blends with the white matter of the flocculus. These curving portions, lateral to the nodulus, are the so-called lateral parts of the velum. Each of these lateral parts, traced into the horizontal fissure, passes above or dorsal to the peduncle of the flocculus (see above), and blends with the under surfaces of the three peduncles to form the white matter of the hemisphere. Thus it is seen that the white matter of the worm is made up of the union of the superior medullary velum above and the central part of the inferior medullary velum below, while that of the hemispheres is the conjointed three peduncles and lateral part of the inferior velum.

**Tent and Lateral Recess.**—The cleft between these layers of white matter is, like them, divisible into a central and two lateral portions. The central part lies between the superior velum above and the central portion of the inferior velum below. It is called the tent, from its pointed appearance on section. The lateral portions, when closed in by the upper ends of the restiform bodies (see page 738), are known as the lateral recesses of the fourth ventricle, while the tent forms the roof of the central part of the fourth ventricle (see page 738).

**Superior Medullary Velum.**—The superior medullary velum, or valve of Vieu- sens, has been partially described. It is a thin lamina of white matter stretched between the inner margins of the superior cerebellar peduncles; it forms the roof of the upper half of the fourth ventricle. It is narrow above, where it passes beneath the lower corpora quadrigemina (mid-brain), and broader below at its connection with the upper veriform process of the cerebellum. A slight elevated ridge, the frænulum, descends upon the upper part of the valve from between the lower corpora quadrigemina, and on either side of it may be seen the fourth nerve. Its lower half is covered by a thin, transversely-grooved lobule of gray matter prolonged from the anterior border of the cerebellum; this is the lingula.

**Arbor Vitæ** (Figs. 428, 429).—This is the name given to the white matter of either worm or hemisphere when viewed on antero-posterior section. On such a section the white matter looks like a tree with a central trunk and branches, with the branches also subdividing into stems. These stems, being surrounded by gray matter, resemble leaves or folia; and there may also be secondary folia whose stems come from a primary stem, and not from the main trunk of white matter. These folia, as already explained (page 728), are merely the cut surfaces of the corresponding lobules, whether of worm or hemisphere. The main trunk of the arbor vitæ of the worm is slender, while that of the arbor vitæ of each hemisphere is thick and bulky. This difference is due to the large amount of white matter resulting from the conjointed peduncles and lateral part of inferior velum as compared with that resulting from the union of the comparatively thin superior velum with the central part of the inferior velum.
Fibres of the Peduncles (Fig. 435).—The fibres of the superior peduncles on entering the hemisphere pass to a great extent into the interior of the corpus dentatum (see below), though some wind round it and reach the gray cortical matter, especially on its inferior surface, while others pass into the white matter of the worm. Into the white matter of the worm pass the fibres of the superior velum, of which certain longitudinal ones are quite distinct. These last are the antero-lateral ascending cerebellar tracts of cord and medulla (see page 717).

The fibres of the middle peduncles on entering the hemisphere have a generally dorsal tendency, after which they go in various directions: the upper fibres of the tuber annulare pass to the lower part of the hemisphere; the lower fibres of the tuber pass into the upper part of the hemisphere; while the remaining fibres (middle of tuber and dorsal transverse; see Pons) pass for the most part into the middle region of the hemisphere.

The fibres of the inferior peduncles on entering the cerebellum are placed between the middle peduncle externally and superior internally. They then pass upward, and radiate into the upper part of the hemisphere, curving over the corpus dentatum; some are extended into the white matter of the worm. These last are the continuations of the direct cerebellar tract.

The fibres already described, which make up the inferior peduncle or restiform body, may be summarized as follows: 1. Direct cerebellar tract; 2. External arciform fibres; 3. Internal arciform fibres (from opposite olivary nucleus); 4. Fibres from accessory cuneate nucleus; 5. Fibres from antero-lateral descending cerebellar tract of cord; 6. Fibres of Solly. These last are occasionally found, and are seen on the surface of the medulla running upward and backward from the direct pyramidal tract of the cord just before it enters the pyramid.

The fibre propria of the cerebellum are of two kinds: (1) commisural fibres, which cross the middle line to connect the opposite halves of the hemispheres, some at the anterior part, and others at the posterior part, of the vermis; (2) arcuate or association fibres, which connect one lamina with another, arching across the fissures between the laminae.

The gray matter of the cerebellum is found in two situations: (1) on the surface, forming the cortex; (2) as independent masses in the interior.

(1) The gray matter of the cortex presents a characteristic foliated appearance, due to the series of laminae which are given off from the central white matter; these laminae give off secondary laminae which are covered with gray matter. This arrangement gives to the cut surface of the organ the foliated appearance already described. Externally the cortex is covered by pia mater, and internally is the medullary centre, consisting mainly of nerve-fibres.
Microscopical Appearance of the Cortex.—The cortex presents a remarkable structure, consisting of two distinct layers—viz. an external gray or cellular layer, and an internal rust-colored granular layer. Between the two layers, or rather situated in the deepest part of the gray or cellular layer, is an incomplete stratum of the characteristic cells of the cerebellum, the corpuscles of Purkinje.

The external gray or cellular layer (Fig. 436) consists of fibres and cells. The fibres are delicate fibrillae, some running at right angles to the surface-fibres of Bergman. These are the dendritic processes of large glia-cells situated in the granular layer. On reaching the periphery these fibres expand into small cones, bases superficially, and here form a delicate supporting connective-tissue-like membrane, which spreads out into a broad base against the inner surface of the pia mater. Other fibres are horizontal, and can be observed to unite, by means of a T- or Y-shaped junction, with the long axis-cylinder processes of the granule-cells in the granular layer.

The cells are small, and are in two layers, outer and inner. All have numerous branching axis-cylinder and protoplasmic processes, the former of which, from the inner cells (basket-cells), give off descending vertical branches which ramify like a basket around the corpuscles of Purkinje.

The corpuscles of Purkinje (Fig. 436) are flask-shaped cells in the deepest part of the external gray or cellular layer, resting against the internal rust-colored
layer. From their under surface a slender axis-cylinder process arises, which passes through the internal layer, and becomes continuous with the axis-cylinder of a medullated nerve-fibre in the medullary (white) substance beneath. From the other extremity a number of protoplasmic processes (dendrites) are given off, which branch in an antler-like manner in the external layer, all having free terminations.

The internal or rust-colored layer (Fig. 436) is characterized by containing multitudes of granular-looking cells. There are also minute stellate cells and glia-cells. Between the cells is a fine nerve-network, with which the processes of all the cells are continuous, except the axis-cylinder processes of the granule-cells.

There are still other fibres to be found in the cerebellar cortex. These come directly from the white centre, and penetrate through the entire cortex. Each fibre, thus penetrating, gives off branches in the granular layer, the ramiﬁces exhibiting peculiar moss-like appendages, hence are called “moss-fibres” (Ramon y Cajal). Other ramifications are also found around Purkinje’s corpuscles. Finally, in the external layer these fibres terminate by becoming longitudinal and horizontal. The cell-origin of these fibres is probably situated in the gray matter of the spinal cord.

(2) The independent centres of gray matter in the cerebellum are—(1) the corpus dentatum; (2) the roof nuclei of Stilling.

The corpus dentatum (Figs. 435, 436), or ganglion of the cerebellum, is situated a little to the inner side of the centre of the stem of white matter. It consists of an open bag or capsule of gray matter, the section of which presents a gray dentated outline, open at its anterior part. It is surrounded by white fibres; white fibres are also contained in its interior, which are derived from the superior peduncles.

The roof nuclei of Stilling are two small gray masses situated in the anterior part of the white matter of the worm, close to where the valve of Vieussens begins to assist in the formation of the roof of the fourth ventricle. These can only be seen in microscopic preparations.

The Fourth Ventricle (Figs. 423, 429).

The Fourth Ventricle, or ventricle of the cerebellum, is the space between the mesial portions of the dorsal surfaces of the medulla oblongata and pons ventrally and the cerebellum dorsally. It consists of a floor, roof, and lateral boundaries.
The floor has already been described in detail. It is flat and lozenge-shaped, its upper half being on the dorsal surface of the pons, its lower half lying between the restiform bodies on the upper portion of the dorsal surface of the medulla. Its widest or central portion is at the junction between pons and medulla. Like the floor, the ventricle itself is divided into an upper, a lower, and a middle portion.

**Boundaries of the Fourth Ventricle.**—The upper portion has for its floor the central part of the dorsal surface of the pons; for its lateral boundaries, the inner surfaces of the superior cerebellar peduncles; for its roof, the superior medullary velum.

The middle portion has for its roof the tent, or space between central part of inferior medullary velum, below; and that part of superior medullary velum which is below the lingula, above; and their line of junction dorsally. The tent, on section, appears pointed, the angle projecting dorsally from pons and medulla into the worm, between lingula above and nodulus below. In the complete ventricle the tent lies dorsal to the widest part of the floor; and the lateral boundaries of this particular region of the ventricle are the lateral angles (see page 723), each lateral angle being the point of contact of the lower end of the inner surface of the superior peduncle with the upper end of the inner surface of the inferior peduncle, just as each peduncle bends dorsally to enter the hemisphere.

The lower portion has for its floor that part of the dorsal surface of the medulla which is between the restiform bodies, and for its lateral boundaries the clavae of the funiculi graciles and the inner surfaces of the restiform bodies. The inner surface of the restiform body is merely the inner aspect of its generally rounded, elevated surface. Hence it is not so marked as that of the flattened superior peduncle, which also has an inner margin, to which is attached the superior medullary velum; while the inner margin of the rounded inferior peduncle would be merely the line drawn between its inner and dorsal aspects. The roof of the lower portion of the fourth ventricle is the tela choroidea inferior, which will now be described, together with the lateral recesses of the fourth ventricle.

**Roof of Lower Portion of Fourth Ventricle; Lateral Recess; Tela Choroidea Inferior.**—In the description of the white matter of the cerebellum, as it lies between the edges of the great horizontal fissure in the anterior notch, it was stated that this white matter was split into two layers, the lower of which is the inferior medullary velum. An important difference between these two layers must now be noted, in addition to the others already given. This difference is that, in the complete specimen, the inferior medullary velum, as such, has a free edge, while the upper layer is continued directly into the prolongations of its component parts, superior medullary velum and the peduncles of the cerebellum.

This free edge of the inferior velum is directed, in the natural position, downward and forward. The free edge of the mesial part lies over the nodulus, which projects somewhat beyond it. Being very thin, it cannot be made out distinctly except on antero-posterior section. The free edges of the lateral portions, however, are well seen on removal of cerebellum from pons and medulla and after separating the edges of the great horizontal fissure. In the complete condition each of these lateral free edges of the velum lies just dorsal to the upper extremity of the corresponding restiform body just before it bends backward into the cerebellum, and curves around it, as it were, reaching out laterally to the floculus, which, in the complete specimen, lies just external to the lateral aspect of the restiform body.

Having thus located the free edge of the entire inferior medullary velum, it now remains to establish its connection with the subjacent parts. This connection is effected by a layer of epithelial cells prolonged from the general epithelial lining of the ventricle. It is understood, of course, that all the ventricles of the brain, as well as the central canal of the cord, are lined with epithelium. Therefore in the fourth ventricle this epithelium lines the under surface of the superior velum; the inner surface of the superior cerebellar peduncle; covers the entire floor, and is also found in the tent and its lateral prolongations. Therefore it
must also cover the upper surface of the entire inferior medullary velum; and it is the prolongation of this particular layer which was just referred to.

The epithelium covering the central part of the inferior velum on arriving at its free edge is continued over the projecting portion of the upper surface of the nodulus, and then bends sharply downward and backward around the anterior extremity of the nodulus, and is continued on down to the calamus scriptorius—i.e., angle of divergence of the clava—where it dips into the upper (medullary) part of the central canal of the cord, and becomes continuous with its dorsal lining epithelium. This layer of epithelium, thus traced from above downward, has, of course, lateral attachments, and on each side this attachment is mainly the line, already referred to, which marks off the inner from the dorsal aspect of the restiform body. Below, this line of attachment is continued down on the clava, and at the calamus scriptorius meets the line from the opposite side. Along this line for its entire extent the layer of epithelium is continuous with the epithelium lining the slightly elevated inner aspect of the restiform body and that covering the floor, but is not prolonged over the dorsal aspect of the restiform body, which is closely invested with pia mater. Owing to the divergence of the restiform bodies and clava, it is evident that this layer of epithelium is triangular in shape, with its apex at the calamus scriptorius. This triangular layer of epithelium is the real roof of the lower portion of the fourth ventricle.

Lateral Recess.—The epithelium covering each lateral portion of the inferior medullary velum on arriving at its free edge is prolonged directly on to the upper extremity of the restiform body, close to which the free edge lies, and is then reflected upward for a very short distance—i.e., to where the restiform body bends backward to enter the hemisphere. The epithelium then bends backward also, covering the (now) under surface of the inferior cerebellar peduncle, and thus enters the lateral portion of the cleft (see page 734) between the “laminae” of the cerebellar white matter; arriving at the bottom of this cleft, it is reflected back again over the upper surface of the lateral part of the inferior medullary velum to its free edge, at which point its tracing was commenced.

The line of attachment of the epithelium to the upper end of the restiform body just after its reflection from the edge of the inferior velum is, of course, directed transversely. Its inner end bends downward and becomes continuous with the line already mentioned on the restiform body, along which the “roof” epithelium blends with that of the side and floor.

Thus is formed the complete lateral recess, which, when all the parts are connected, is really a triangular-shaped, tunnel-like prolongation of the cavity of the fourth ventricle, curving around the extreme upper end of the restiform body just before that body bends backward into the hemisphere of the cerebellum.

The outer extremity of the lateral recess may be regarded as a pointed cul-de-sac. At its inner extremity is an aperture through which its lining epithelium is continuous with that of the fourth ventricle. This aperture is situated just at the lateral angle (see above) of the ventricle. The cul-de-sac is situated just between the flocculus externally and the outer aspect of the restiform body internally.

Tela Choroidea Inferior.—The pia mater which invests the inferior worm is continued upward and forward, dipping in and out of the various fissures, until it reaches the nodulus. It now closely invests the nodulus and bends sharply around it, forward, upward, and a little backward, following exactly the course of, but lying posterior to, the epithelial roof of the ventricle, already described, until it reaches the free edge of the inferior velum lying on the nodulus. At this point it is reflected at an acute angle right back on itself, and now follows the “epithelial roof” down to the calamus scriptorius. In its course this reflected layer of pia mater lies, naturally, dorsal to the epithelial roof, and so closely adherent to it that the two form one structure. This structure is the tela choroidea inferior. It is the practical roof of the lower portion of the fourth ventricle, because when the pia mater is pulled away the epithelial layer comes with it, and thus this portion of the ventricle is exposed.
THE NERVOUS SYSTEM.

If the pia mater covering the hemisphere on each side of that covering the inferior worm (the lateral extension of the same layer) be traced, it will be found to follow a similar course, thus: After passing upward it reaches the under surface, and then the free edge, of the lateral part of the inferior velum. It is now sharply reflected on itself, and passes downward on the dorsal aspect of the restiform body. This is merely the lateral extension of the pia materal portion of the tela choroidea inferior. As this layer passes from the edge of the inferior velum (lateral part) to the restiform body it is in contact, just at its downward bend, with the epithelium of the lateral recess just where it is being reflected on to the extreme upper end of the restiform body. It is therefore evident that along the free edge of the entire inferior medullary velum there is attached a margin of pia mater consisting of two layers folded on themselves. For some distance downward these two layers are somewhat adherent to each other.

The Ligula.—In the fourth ventricle, as well as in the other ventricles, the lining epithelium has between it and the surrounding brain-tissue a delicate layer of neuroglia known as the ependyma. The upper surface of the inferior velum also has on it some of this ependyma. At the free edge of the velum, however, this ependyma ceases abruptly, and the epithelium comes in direct contact with the pia mater. But where the epithelium leaves the pia mater to be reflected upward on the restiform body (lateral recess), or where it leaves the under surface of the tela choroidea inferior to be reflected on the inner aspect of the restiform body and floor of the ventricle, the ependyma reappears. Hence this edge of ependyma follows the line of reflection of epithelium all the way from the calamus scriptorius obliquely upward and outward, and then outward around the upper end of the restiform body. It is not visible to the naked eye until the pia mater is pulled away. This tearing away of the pia mater necessarily brings with it the epithelium lining it, and there is seen a very delicate, jagged line of tissue following the course of the "line of reflection" just described. This line of tissue is the edge of the ependyma plus the torn edge of epithelium, and is the ligula, not to be confounded with the lingula. The union of the lower ends of the two ligula in the calamus scriptorius is known as the obex.

This tearing away of the pia mater and epithelium also brings into view the free edge of the inferior medullary velum, especially its lateral portions on each side of the nodulus.

Choroid Plexuses.—The under surface of the pia-matral portion of the tela choroidea inferior is not smooth. It has a linear series, on each side of the middle line, of minute vascular tufts of pia-mater tissue projecting ventrally. These tufts, however, do not pierce the epithelial "roof," but are covered, ventrally, everywhere by the epithelium. These lines of tufts with their epithelium are the choroid plexuses of the fourth ventricle.

Similar, but longer, tufts of pia-mater tissue are also prolonged from the pia mater which lies beneath the epithelium, closing in the lateral recess. These last are collected into quite a distinct bunch, resembling a group of small villi, which is seen between the flocculus and outer aspect of the restiform body. In the middle of these villi is the pointed cul-de-sac of the lateral recess, which by some observers is said to be perforated by a minute foramen.

A similar foramen is said to be present in the tela choroidea inferior just above the calamus scriptorius. This is the so-called foramen of Majendie.

THE MID-BRAIN (Figs. 415, 416, and 439).

The mid-brain, or mesencephalon, is that portion of the brain which connects the pons Varolii below with the cerebrum (inter-brain and hemispheres) above. On this account it is sometimes called the isthmus or the crus cerebri. It has four surfaces—a superior, an inferior, a dorsal, and a ventral. The first two are flattened and are attached, the superior to the cerebrum, the inferior to the pons. They are also nearly parallel with each other. The two latter are somewhat curved
These oculomotor acusticus anterior annulare tegmentum. An
stantia margin upward. Ttero-superior) in looking downward
substantia nal of the mid-brain is the smallest of all the brain
ventricles." It is called the aqueduct of Sylvius, and is a mere tube whose
diameter is very small compared to the bulk of the mid-brain in which it lies. It
is situated close under the dorsal surface in the middle line; hence its direction
is upward and forward. It opens below into the fourth ventricle and above into
the third ventricle.

Main Divisions.—The mid-brain, as a whole, is divided into two portions (Fig.
440), a postero-superior and an antero-inferior, by a lamina of gray matter, the
substantia nigra, which is seen to be convex downward and from side to side in sections
made both dorso-ventrally and from above downward. Hence this lamina, as a whole, has
an antero-posterior curve, with the concavity looking ventrally. Its two edges lie along and
in the sulcus lateralis.

All of the mid-brain dorsal to and above (postero-superior) the substantia nigra is called the
tegmentum, while that portion which is below and anterior (antero-inferior) is known as the crustae.

Crustae.—There are two crustae, which diverge from each other from below
upward. The lower end of each is overlapped by the upper margin of the tuber
annulare of the pons. Each crusta is a thick, wide, rounded bundle of longitudi-
nal white fibres, its outer margin being limited by the sulcus lateralis. Its inner
margin is free, and in the interval between it and the opposite crusta is the sub-
stantia nigra passing across. Dorsal to each crusta is the substantia nigra, and
on the inner margin of each, where the substantia nigra is about to cross over, is
a groove, the mesial sulcus, or sulcus oculo-motorius, out of which the roots of the
third nerve pass. The two *crusta* are often spoken of as the *crura* or *pedunculi cerebri*.

**Fibres of the Crusta.**—These are—(1) the upward continuations of the fibres of the pyramids, *pyramidal tract*, which in passing through the pons are known as its ventral longitudinal fibres: this pyramidal tract forms about the *middle third* of the crista. Superiorly, it is continued into the middle part of the internal capsule of the hemisphere, and thence to the fronto-parietal or Rolandic region of the cortex. (2) The *direct sensory tract*: these fibres occupy the *outer third* of the crista; below, they probably come from the nuclei pontis; above, they pass into the posterior part of the internal capsule, and thence to the cortex of the occipito-temporal regions of the hemisphere. (3) Fibres of the *inner third* of the crista: the lower origin of most of these is not well defined. They possibly arise from the cells of the substantia nigra. Above, they pass through the anterior part of the internal capsule to the cortex of the prefrontal region of the hemisphere. One bundle, however, is distinct. It is the *mesial fillet* (see below). As it passes upward it crosses obliquely outward through the other fibres of the crista, and its fibres are finally lost in the subthalamic region, where they probably become continuous with the *ansa lenticularis* (see page 747). Below, it is one of the three divisions of the *fillet*.

The *substantia nigra* or *locus niger* is, as already mentioned, a lamina of gray matter situated between the crista and tegmentum and projecting here and there between the bundles of the former. It is thicker at the inner than at the outer side, and is traversed in its mesial part by the fibres of origin of the third nerve. It contains irregular nerve-cells, in which are lodged numerous dark pigment-granules. The portion between the crista, together with the crista, form the *ventral surface* of the mid-brain, which, on each side, is limited by the *sulcus lateralis*.

The *Tegmentum*.—This comprises all that part of the mid-brain *dorsal to* and *superior to* the substantia nigra. Its longitudinal fibres run up through the "dorsal" part, and then bend forward in the "superior" part, from which they pass to their destination. There are really two *tegmenta*, but each is united with its fellow of the opposite side by a prolongation of the median septum or raphe of the pons.

The tegmentum consists of longitudinal bundles of white fibres interlaced by transverse fibres, together with a quantity of gray matter with scattered nerve-cells. It forms a well-marked *formatio reticularis* similar to that found in the pons and medulla, with which it is continuous, receiving, however, a bundle of fibres (*superior peduncle*) from the cerebellum.

The most distinct of the *longitudinal fibres* comprise the following bundles, whose course in medulla and pons has already been described: (1) The *posterior longitudinal bundle*: this lies on each side of the median line and just below the aqueduct of Sylvius. In the mid-brain it gives off fibres to the nuclei of the third and fourth cranial nerves, and receives fibres, in the pons, from the nucleus of the sixth. At the junction between the dorsal and superior surface of the mid-brain each posterior longitudinal bundle passes *dorsal to* the aqueduct and across to the opposite side in the *posterior commissure*; some fibres, however, pass to the subthalamic region of the same side; there are also decussating fibres between the two "bundles" in the raphe. (2) The *fillet*: its mode of origin and course in the medulla and pons have been described. Arrived at the mid-brain, it divides into *three subdivisions*—the *mesial fillet*, the *upper fillet*, the *lower* or *lateral* fillet. The first has already been described with the crista. The upper fillet passes to the superior corpus quadrigeminum. The *lower* fillet appears on the *dorsal surface* (see below). Above, its fibres pass to the inferior corpus quadrigeminum, being reinforced by some fibres from the superior medullary velum. It also receives, through the trapezium of the pons, some fibres from the ventral auditory nucleus of the opposite side. (3) *Fibres from the superior peduncle of the cerebellum*: these on leaving the pons dip ventrally, and beneath the corpora
quadrigemina the fibres of each peduncle decussate with each other, so that fibres from one half of the cerebrum are continued in the other half of the cerebellum. The fibres thus pass upward into the optic thalamus, surrounding, as they go, the red nucleus, from and to the cells of which they receive and give fibres.

(4) Certain fibres from the olivary nucleus of the medulla: above, these are traceable into the internal capsule of the hemisphere.

The red nucleus (Fig. 451), or nucleus of the tegmentum, is a cylindrical mass of gray matter on each side of the middle line. On cross-section it is seen as a reddish circle in about the middle of the tegmentum ventral to the aqueduct of Sylvius.

The following structures are all grouped on the dorsal surface of the mid-brain. They belong to the tegmentum, since they are dorsal to the substantia nigra. This dorsal surface is limited by the sulcus lateralis on each side.

The corpora or tubercula quadrigemina are four rounded eminences placed in pairs, two in front and two behind, and separated from one another by a median longitudinal and a transverse groove.

They are situated immediately behind the third ventricle and posterior commissure, and beneath the posterior border of the corpus callosum. Below, they rest upon a layer of white matter, the quadrigeminal lamina, immediately beneath which, in the median line, is the aqueduct of Sylvius. The anterior or upper pair are the larger, oblong from before backward, and of a gray color. The posterior or lower pair are hemispherical in form and lighter in color than the preceding. From the outer side of each of these eminences a prominent white band, termed brachium, is continued. Those from the anterior pair (brachia anteriors) are long and slender, and each passes at first obliquely outward, and then curves backward, downward, and forward around the posterior extremity of the optic thalamus, which overhangs it, and then between the inner and outer geniculate bodies into the optic tract. Those from the posterior pair (brachia posteriors) are comparatively short and broad, and each passes to an oval prominence, the internal geniculate body, beneath which it apparently disappears. Both pairs of these bodies are composed of white matter externally and gray matter within. In fishes, reptiles, and birds these bodies are only two in number, and are called the optic lobes, from their connection with the optic nerves; but in mammals they are four in number, as in man. In the human fæetus they are developed at a very early period, and form a large proportion of the cerebral mass.

These bodies are apparently connected with the cerebellum by means of the superior peduncles of the cerebellum, which are continued onward to the optic thalamus through the tegmentum, as already mentioned.

Arching over the upper ends of these peduncles is a flattish triangular-shaped band of white fibres, the lemniscus or lower fillet, which issues from beneath the transverse fibres of the pons to pass obliquely round the upper end of the superior peduncle of the cerebellum and become lost in the inferior quadrigeminal body.

The corpora geniculata are two small, flattened, oblong masses, placed on the under and back part of each optic thalamus, and named from their positions, corpus geniculatum externum and internum. The two bodies are separated from one another by the brachium anterius from the anterior corpus quadrigeminal.

Structure of the Corpora Quadrigemina and Geniculata.—The peripheral gray matter of the corpora quadrigemina differs somewhat in the posterior and anterior bodies. The posterior are composed almost entirely of gray matter, covered over by a thin stratum of white matter, and separated from the central gray matter of the aqueduct by tracts of transverse white fibres derived from, and forming part of, the lower fillet. The anterior are covered superficially by a thin stratum of white matter; beneath this is a layer of gray matter, termed the stratum cinereum, and consisting, as well as the gray matter of the posterior lobes, of small multipolar cells imbedded in a fine network of nerves. Beneath this, again, is a characteristic mass of gray matter, termed the stratum opticum,
which is made up of fine nerve-fibres, coursing in a longitudinal direction, and containing between them small masses of gray substance, consisting of small multipolar nerve-cells imbedded in gray matter. Lastly, between this body and the central gray matter around the Sylvian aqueduct is a thin lamina of white matter, derived from the upper fillet.

The *geniculate bodies* are continuous with the gray substance of the optic thalamus, and the external one (*corpus geniculatum externum*) is peculiar on account of its dark color, due to its cells containing pigment. It presents a laminated arrangement, and consists of alternate thick layers of gray matter and thin layers of white matter. Its cells are multipolar. The internal body (*corpus geniculatum internum*) is of lighter color, does not present a laminated arrangement, and its cells are smaller in size and fusiform in shape. These bodies, strictly speaking, belong, the *external* to the inter-brain, and the *internal* to the mid-brain.

The *locus niger*, or gray matter of the crus cerebri, like the external geniculate body, is peculiar from the large number of dark pigment-granules which are contained in its ganglion-cells, and which give to it its dark color, from which it has derived its name. Its cells are small and multipolar.

The *Aqueduct of Sylvius*—This is the "ventricle" of the mid-brain. It is a narrow tube into which the fourth ventricle opens below, and which opens into the third ventricle above. Hence it is sometimes called the *iter a tertio ad quartum ventriculum*. It is a little over half an inch long. It lies in the tegmentum, and its course is upward and forward, the same direction as that of the *dorsal surface* of the tegmentum, on which the groove between the right and left corpora quadrigemina indicates its position. It lies immediately ventral to this groove. Its *roof* is the lamina quadrigemina, the white layer which supports the corpora quadrigemina, and into which are prolonged the fibres of the superior medullary velum. Its shape, on transverse section, varies, being T-shaped near the fourth ventricle, shield-shaped about midway in its course, and triangular near the third ventricle, into which it opens just at the bend between end of dorsal surface and beginning of the superior surface of the mid-brain.

In all cross-sections through the aqueduct—*i. e.* at right angles to the plane of the dorsal surface, from its beginning to end—a *large amount of tegmental tissue* is to be seen between it and the *substantia nigra*, ventrally. Hence the latter can have nothing to do with the formation of the floor of the aqueduct.

The *central gray matter* surrounding the Sylvian aqueduct presents some features requiring especial mention. It forms a tolerably thick layer surrounding the canal, but is thicker on the lower wall—that is, below the canal—than above. The cells, which are multipolar, are here collected into groups, and form *nuclei* for the *origin* of the *third* and *fourth* cranial nerves. The *nucleus* for the third and fourth consists of a column of cells of large size on either side of, and close to, the median line. In addition to these cells there are found at the periphery of the zone of gray matter surrounding the aqueduct some other, and larger, cells, sometimes single, sometimes grouped in twos or threes, or even more. They are globular, and lie in the midst of well-marked nerve-fibres, with which their processes appear to be continuous. Close to the lateral margin of this gray matter, in its lower part, is the upper end of the *upper nucleus* of the fifth nerve.

The *third nerve* passes from its nucleus in a somewhat curved manner through the tegmentum, and emerges from the oculo-motor groove on the inner margin of the crusata. Some of its fibres, however, from the dorsal part of the nucleus, decussate.

The *fourth nerve* passes downward from its nucleus toward the pons, on entering which it turns *dorsally*, and then runs transversely in the *superior medullary velum*, crossing the middle line and decussating with its fellow, to emerge from the dorsal surface of the velum. It then curves obliquely downward and forward, resting on the *crusta*. 

---

**THE NERVOUS SYSTEM.**
Superior Surface of Mid-brain.—The superior surface of the mid-brain begins just anterior to the anterior pair of the corpora quadrigemina. It is directed downward and forward, and meets the upper extremity of the ventral surface at quite an acute angle. The central portion of this surface is narrow and free. It consists of tegmentum, and forms the first part (from behind forward) of the floor of the third ventricle (Fig. 442). Of each lateral portion the area immediately adjacent to the central portion is also tegmentum, and has resting on it and is closely connected with the optic thalamus of the inter-brain. External to this area is the “margin” of the superior surface, which, when the mid-brain is isolated by dissection, is seen to consist of the upper ends of the fibres of the crista, cut across just as they are about to be continuous with those of the internal capsule of the hemisphere (see Figs. 460 and 461).

Posterior Perforated Lamina.—In vertical transverse sections through the posterior part of the optic thalami and superior surface of the mid-brain the tegmentum is clearly to be distinguished, both the portions beneath the optic thalami and the central free portion between them (beginning of floor of third ventricle). In all similar sections made anterior to this, however, the tegmentum is seen to become less and less distinct, until it finally disappears, and we have only the optic thalami lying dorsal to the substantia nigra, which last also bridges over the interval (third ventricle) between them. This portion of the substantia nigra is the anterior part of that (already mentioned) which is seen in the interval between the crista. It is called the posterior perforated lamina, and is the second structure, from behind forward, forming the floor of the third ventricle.

Subthalamic Region.—The gradual disappearance of the tegmentum in the cross-sections just referred to is due to the blending of the tegmental tissue with that of the superjacent portion of the optic thalamus, the central tegmental tissue also thinning out as the lateral parts are thus absorbed. To this tissue, thus made up of tegmentum and optic thalamus, the name subthalamic tegmental region is given. In it are seen the remnant of the red nucleus on each side, together with what corresponds to the lateral parts of the substantia nigra—nucleus of Luys. Dorsal to this is the zona incerta, a layer of reticular formation derived from that of the tegmentum proper, and still more dorsally is the striatum dorsale, a layer of longitudinal fibres derived from the posterior longitudinal bundle and superior peduncle of the cerebellum (see page 742).

THE INTER-BRAIN (Fig. 441).

The inter-brain, or thalamencephalon (i.e. thalamencephalon proper and prosencephalon, see page 706), together with the hemispheres, constitutes the cerebrum.

Anteriorly, the inter-brain is connected with the combined frontal lobes of each hemisphere; laterally, it is connected with the inner aspect of each hemisphere; superiorly, it has resting on it, but with two layers of pia mater interposed, the under surface of the combined hemispheres; posteriorly, it is connected, mesially, with the lamina quadrigemina of the mid-brain, beyond which connection, on each side, it is free, this free portion being the rounded posterior extremity pulvinar of the optic thalamus.

The cavity of the inter-brain is the third ventricle, a vertical antero-posterior slit lying between the optic thalami, which are the thick side-walls of the inter-brain (see also Figs. 447 and 451). The roof proper of the ventricle is a layer of epithelium, like that of the lower half of the fourth ventricle, which stretches between the optic thalami, and, together with their superior surfaces, constitutes the upper surface of the inter-brain. Hence (see above) the under surface of the combined hemispheres lies, in the middle line, on the roof of the third ventricle, but with two layers of pia mater (velum interpositum) interposed. The floor of the third ventricle almost meets the roof posteriorly, being separated from it only by the orifice of the Sylvian aqueduct, and then proceeds downward and forward until it attains its greatest distance from the roof (infundibulum), where it turns upward and forward, and finally upward to meet the anterior end of the roof.
proper. This "upward prolongation" of the floor is known as the "anterior boundary" of the ventricle.

The Optic Thalamus.—Each optic thalamus is a large oblong mass of, chiefly, gray matter. It has two rounded extremities, anterior and posterior, and four surfaces, superior, inferior, external, and internal.

The inferior surface rests upon, and is united with its corresponding part of the tegmentum. The external surface lies in contact with the internal capsule of the hemisphere. Its internal surface forms the lateral boundary or wall of the

---

**Fig. 441.—Superior surface of inter-brain; dorsal surfaces of mid-brain, pons, and medulla. Most of the cerebral hemispheres and cerebellum are removed, X 1/4. (Gegenbaur.)**

third ventricle (Figs. 447, 442, 441). Its upper surface is free, and is traversed by a groove from behind forward and inward. The portion external to this groove is seen in the floor of the body of the lateral ventricle, but it is covered by a layer of epithelium continuous with that lining the lateral ventricle. It is marked in front by an eminence, the anterior tubercle. The portion of the upper surface internal to the groove is covered by the velum interpositum.

The posterior extremity of the optic thalamus projects beyond the level of the corpora quadrigemina, and forms a well-marked prominence, the posterior tubercle or pulvinar in close connection with which are two small rounded eminences, the internal and external geniculate bodies, the internal lying in the groove between the dorsally projecting pulvinar and side of the mid-brain, the external being placed
immediately beneath the pulvinar (Figs. 439 and 443). Its anterior extremity, which is rounded and smaller than the posterior, forms the posterior boundary of the foramen of Monro.

**Structure of the Optic Thalamus.**—The optic thalamus is chiefly formed of gray matter, covered over by a superficial layer of white, which on the outer side (external medullary lamina) separates it from the internal capsule. This layer on the upper surface is known as the stratum zonale, and is prolonged downward on the internal surface.

The gray matter is arranged in two masses, the outer and inner nuclei, partially divided by a vertical white septum, S-shaped on section, the internal medullary lamina. The thalamus is traversed by numerous nerve-fibres, which for the most part have no definite direction: some, however, converge and form various bundles which pass out of the optic thalamus to blend with the white matter of the hemispheres, as follows: (1) from its anterior extremity to the frontal lobes (anterior stalk of thalamus); (2) from its lower part (subthalamic region) to (a) lenticular nucleus of corpus striatum (ansa lenticularis) and (b) internal capsule (ansa peduncularis), the fibres of which pass below the lenticular nucleus and into the "external capsule" of the hemisphere; (3) from its outer surface through internal capsule to parietal and temporal lobes; (4) from pulvinar (outer aspect) to occipital lobe. These last are long and curve backward, and radiate toward the cortex. They are called the optic radiations. They connect, through the pulvinar, with the outer root of the optic tract. The gray matter contains comparatively large nerve-cells, both multipolar and fusiform. The inner nucleus is connected
across the middle line with the inner nucleus of the opposite side by the middle commissure of the third ventricle. The outer nucleus is continued into the pulvinar.

There are two other smaller nuclei in the optic thalamus—one the nucleus of the anterior tubercle, and the other, just beneath the trigonum habenulae (see below), the ganglion of the habenula. There are also two bundles of fibres in addition to those just described. One of these runs through the anterior part of the optic thalamus. It is the anterior pillar of the fornix, and will be again referred to, as will also the other, much smaller, the bundle of Vicq d’Azyr, whose fibres run downward from their origin in the cells of the nucleus of the anterior tubercle, just mentioned.

The third ventricle (Figs. 442, 447, 451) is the fissure placed between the optic thalami and extending to the base of the brain. It is bounded, above, by the posterior commissure and the under surface of the velum interpositum, lined with epithelium, from which are suspended the choroid plexuses of the third ventricle. Its floor, somewhat oblique in its direction, is formed, from before backward, by the lamina cinerea, the tuber cinereum and infundibulum, the locus perforatus posticus (posterior perforated lamina) and behind these by the tegmentum of the mid-brain; its sides are formed by the internal surfaces of the optic thalami. It is bounded, in front, by the lamina cinerea, while the extreme upper part of its “anterior boundary” is a layer of epithelium covering, posteriorly, and through which are seen, from within the ventricle, the anterior pillars of the fornix and middle part of the anterior commissure.

These last-named structures belong to the hemispheres, and the epithelium covering them posteriorly is the same layer as that which lies in contact with the lamina cinerea, which itself, on reaching the anterior commissure, passes in front of it, and is continuous with the corpus callosum of the hemispheres. This extreme upper part of the lamina cinerea is often called the lamina terminalis. It is the representative in the adult brain of the anterior end of the primary fore-brain, around and in front of which have grown the anterior parts of the hemisphere vesicles to form the frontal lobes of the hemispheres.

The lateral extension of this epithelial layer is through the corresponding foramen of Monro, which lies just behind each anterior pillar of the fornix.

The various structures which enter into the formation of the third ventricle will now be described more in detail, beginning with those of the roof (Fig. 442).

The posterior commissure is a distinct rounded bundle of white fibres running transversely just above the opening of the Sylvian aqueduct. The pineal gland is placed above it and connected to its upper surface. It is made up of: (1) the combined upper ends of the two posterior longitudinal bundles (see tegmentum of mid-brain) as each bends to the opposite side in order to pass through the opposite optic thalamus and reach the white substance of the hemisphere; (2) commissural fibres between the optic thalami; (3) fibres from one anterior corpus quadrigemini to the opposite upper fillet.

The pineal gland (epiphysis cerebri), so named from its peculiar shape (pinus, a fir-cone), is a small reddish-gray body, conical in form (hence its synonym, conarium), placed immediately behind the posterior commissure and between the anterior corpora quadrigemina. It is retained in its position by a duplication of pia mater derived from the under layer of the velum interpositum, which almost completely invests it. The pineal gland is about four lines in length and from two to three in width at its base, and is said to be larger in the child than in the adult, and in the female than in the male. Its base is connected to the optic thalami by a stalk, which consists of two laminae, an upper and a lower, the intervening space, apex toward the gland, being known as the pineal recess. The lower or ventral lamina is derived from the lower aspect of the posterior commissure, and is reflected upward and backward to meet the upper or dorsal layer at the base of the gland. The dorsal lamina is the direct continuation backward of the epithelial roof of the third ventricle. When this is torn away the dorsal
lamina necessarily has a free edge looking forward. On each side this lamina is
prolonged into a somewhat triangular-shaped, depressed area on the upper surface
of the optic thalamus, known as the trigonum habenula, because the word “ha-
benula” (bridle) is often applied to this dorsal lamina of the stalk. The free edge
of the lamina is also prolonged as a delicate whitish band on to the optic thalamus,
on which it runs forward along the sharp margin which separates the superior
from the internal surface of the thalamus. These bands are the pineal striæ or
peduncles of the pineal gland. Anteriorly each blends with the corresponding
anterior pillar of the forni
x.

Structure.—The pineal gland consists of a number of follicles lined by epithe-
lium and connected together by ingrowths of connective tissue. The follicles
contain a transparent viscid fluid, and a quantity of sabulous matter, named
acereulus cerebri, composed of phosphate and carbonate of lime, phosphate of
magnesia and ammonia, with a little animal matter. These concretions are
almost constant in their existence, and are found at all periods of life. At times
the sabulous matter is found upon its surface, and occasionally upon its peduncles.
In the fœtal brain the pineal gland is a hollow protrusion from the posterior part
of the roof of the inter-brain.

The Epithelial Roof.—This stretches across the third ventricle from one pineal
stria to the other, and then is reflected downward to become continuous with the
epithelium covering the side of the ventricle (internal surfaces of thalami). The
epithelium is not continued on to that part of the superior surface of the thala-
mus which is adjacent to the pineal stria, and which is internal to the oblique
shallow groove, already referred to, which runs along this surface. External to
the groove, however, this upper surface is covered by epithelium, but this epithe-
lium belongs to the lateral ventricle.

The roof epithelium of the third ventricle is continued anteriorly between the
pineal stria until just before they join the down-curving anterior pillars of the
fornix, where it is interrupted by the foramen of Monro, around the margin of
which it passes into continuity with the epithelium, lining its own ventricle and the
lateral ventricle.

The velum interpositum (Fig. 458) is a vascular membrane, a prolongation
from the pia mater. It is of a triangular form, and separates the under surfaces
of the body of the fornix, posterior pillars of the fornix, and posterior part of
corpus callosum above (the last-named structures representing the “under surface
of the combined hemispheres”), from the cavity of the third ventricle and the
inner portions of the superior surfaces of the optic thalami below. Its anterior
extremity, or apex, is bifid, each bifurcation lying close to and behind the corre-
sponding anterior pillar of the fornix, and hence “in,” but covered by epithelium,
the foramen of Monro. Its base lies beneath the posterior rounded border of the
corpus callosum above, and the optic thalami, the corpora quadrigemina, and
pineal gland below.

The velum interpositum is composed of two layers of pia mater, which sepa-
rate from each other at its base, the upper layer passing backward on the under
surface of the occipital lobes of the hemispheres, the lower layer passing down-
ward over the mid-brain, pons, and cerebellum. At the apex the two layers are
continuous with each other, as well as at the margins, which are free and lie along
and project a little beyond the groove, already referred to, which runs forward and
inward on the superior surface of the thalamus. Along this margin is the
choroid plexus of the lateral ventricle, which is covered by the mesial prolongation
of the layer of epithelium covering the outer portion of the upper surface of the
thalamus. After investing the margin of the velum interpositum the epithelium,
still prolonged mesially, is attached to the edge of the fornix, under which the
velum lies and beyond which it projects. As will be seen later, the fornix forms
part of the floor of this district of the lateral ventricle; hence the roughened
thickened margin (choroid plexus) of the velum interpositum really invaginates
into the lateral ventricle, that part of its floor which has become thinned out to a
layer of epithelium, and which stretches from the edge of the fornix outward over the thalamus (outer part of its superior surface) to the tænia semicircularis (a structure forming part of the floor of the lateral ventricle), which lies along that margin of the optic thalamus which separates its superior from its external surface.

**Tela Choroidea Superior.**—From the preceding it is clear that the under layer of the velum interpositum has three districts—a mesial and two lateral, the latter resting on the upper surfaces of the thalami, the former on the “roof epithelium” of the third ventricle, with which it forms practically one membrane. This membrane is the tela choroidea superior, and is exactly similar to the tela choroidea inferior of the fourth ventricle.

The reason, on embryological grounds, for the existence of two layers of the velum interpositum will be given in describing the choroid plexuses of the lateral ventricles.

Of the structures forming the floor (Figs. 442, 446) of the third ventricle, the tegmentum of the mid-brain has been described. The rest of the floor, including the “anterior boundary,” is a gray lamina prolonged from the substantia nigra, and its ventral surface appears at the base of the brain, where, however, the tegmentum cannot be seen (Fig. 473). Various portions of this lamina have received different names. Each of these will now be considered, beginning posteriorly.

The posterior perforated lamina succeeds the tegmentum. It is the anterior part of that portion of the substantia nigra which appears in the interval between the diverging crustae of the mid-brain on each side and the upper margin of the tuber annulare of the pons Varolii posteriorly and below. Together with that portion it is often called the posterior perforated space (pons Tarini). It reaches forward as far as the mamillary tubercles, beyond which the gray lamina is known as the tuber cinereum.

The “space” is perforated by numerous small orifices for the passage of the postero-median ganglionic branches of the posterior cerebral and posterior communicating arteries.

The corpora albicantia, or mamillaria, or mamillary tubercles, are two small, round, white masses, each about the size of a small pea, placed side by side immediately behind the tuber cinereum. Each projects downward from the under surface of the optic thalamus, the exceedingly narrow interval between them being bridged over by a gray commissure continuous with the posterior perforated lamina behind and the tuber cinereum in front. Each is composed externally of white substance and internally of gray matter, the gray matter of the two being connected by the transverse commissure of the same material just mentioned.

The fibres of the white substance terminate in the cells of the gray matter, and they are derived from two distinct bundles: one, deeply situated in the substance of the optic thalamus, is the bundle of Vieg d’Azyr, already mentioned; the other, much larger, is the anterior pillar of the fornix, which, after bending sharply downward around the foramen of Monro, passes obliquely, downward and backward, through the substance of the anterior portion of the thalamus, to terminate in, and thus help to form, the corresponding corpus albicans or bulb of the fornix. In its course through the thalamus it lies quite near the internal surface, and may even cause a slight projection on the side of the third ventricle.

The tuber cinereum is the next portion of the general lamina of the floor. It is wider than the posterior perforated lamina, and blends laterally with the substance of the lower and anterior part of the thalamus, while antero-laterally, passing dorsal to the optic tract, it extends beyond the limits of the thalamus into the gray matter of the anterior perforated space on the under surface of the hemisphere. Anteriorly, it is attached to the posterior edge of the optic commissure. From the middle of its under surface a conical tubular process of gray matter, about two lines in length, is continued downward and forward, to be attached to the posterior lobe of the pituitary body: this is the infundibulum. Its canal, which is funnel-shaped, communicates with the third ventricle.
The pituitary body (hypophysis cerebri) is a small reddish-gray vascular mass weighing from five to ten grains, and of an oval form, situated in the sella Turcica, in connection with which it is retained by a process of dura mater derived from the inner wall of the cavernous sinus. This process covers in the pituitary fossa, enclosing the pituitary body, and having a small hole in the centre through which the infundibulum passes. The pituitary body is very vascular, and consists of two lobes, separated from one another by a fibrous lamina. Of these, the anterior is the larger, of an oblong form, and somewhat concave behind, where it receives the posterior lobe, which is round. The two lobes differ both in development and structure. The anterior lobe, of a dark, yellowish-gray color, is developed as a tubular prolongation of the epiblast of the buccal cavity, and resembles to a considerable extent, in microscopic structure, the thyroid body. It consists of a number of isolated vesicles and slightly convoluted alveoli lined by epithelium and united together by connective tissue. The epithelium is columnar, and occasionally ciliated. The alveoli sometimes contain a colloid material similar to that found in the thyroid body, and their walls are surrounded by a close network of lymphatics and capillary blood-vessels. The posterior lobe is developed by a hollow outgrowth from the embryonic brain, and during fetal life contains a cavity which communicates through the infundibulum with the cavity of the third ventricle. In the adult it becomes firmer and more solid, owing to the growing in of a sponge-like connective tissue arranged in the form of reticulating bundles, between which are branched cells, some of them containing pigment.

The lamina cinerea begins at the posterior border of the optic commissure, in continuity with the tuber cinereum. It passes forward and downward over the commissure, to which it is adherent, and then turns upward, forms the anterior boundary of the third ventricle, and terminates, as the lamina terminalis, by blending with the middle portion of the anterior extremity of the corpus callosum. It is continuous on each side with the gray matter of the anterior perforated space. The angle made by the upward bend of the lamina is known as the optic recess.

The anterior boundary of the third ventricle is the lamina cinerea below; above this, for a very short distance, the anterior boundary is the layer of epithelium covering portions of the posterior aspects of the anterior commissure and anterior pillars of the fornix, as already explained.

The sides of the ventricle are the internal surfaces of the thalami. Each is slightly convex, and just in front of the middle point of each is attached the corresponding extremity of the middle commissure, a band of gray matter which passes right across the ventricle. It is frequently broken in examining the brain, and might then be supposed to be wanting. A little more anteriorly is seen a somewhat curved, from above downward and backward, elevation (anterior pillar of fornix already explained). As these pillars, traced upward, become free, they bend sharply upward and backward, thus forming a completed curve, each enclosing in front and above the foramen of Monro, which has for its posterior boundary a part of the anterior extremity of the optic thalamus.

Antero-inferiorly to the curved elevations is still, on each side, a small portion left of the internal surface of the thalamus, connected to the similar opposite portion. below and in front, by the tuber cinereum and lamina cinerea. It is thus seen that all these structures really form the anterior extremity of the third ventricle (see page 706), which is the prosencephalon, or, in the fetal brain, the first secondary cerebral vesicle. Hence the “curved elevations” may be regarded as indicating, approximately, the line of division or constriction between the first and second secondary cerebral vesicles (prosencephalon and thalmencephalon proper), while the foramina of Monro are to be regarded as opening from the prosencephalon, and thus represent the fetal foramina caused by the bulging out of the hemisphere vesicles (see Figs. 412, 413, 414).

The choroid plexuses of the third ventricle, formed like those of the fourth, lie along the roof, projecting downward, one on each side of the middle line.
They are covered with epithelium, and are derived from the lower layer of the velum interpositum. Of the arteries of the velum interpositum, some branches from the superior cerebellar and posterior cerebral enter from behind beneath the corpus callosum. The veins of the velum interpositum, the venæ Galeni, two in number, run between its layers; they are formed by the venæ corporis striati and the veins of the choroid plexuses; the venæ Galeni unite posteriortly into a single trunk, which terminates in the straight sinus (Fig. 383).

Openings.—The third ventricle has four openings connected with it. In front are the two foramina of Monro, one on each side, through which the third communicates with the lateral ventricles. Behind is a third opening, that of the aqueduct of Sylvius, or iter a tertio ad quartum ventriculum. The fourth, situated in the anterior part of the floor of the ventricle, is a deep pit, which leads downward to the funnel-shaped cavity of the infundibulum (iter ad infundibulum). A fifth opening exists in the foetus which communicates behind with the cavity in the pineal gland.

The lining membrane of the lateral ventricles is continued through the foramen of Monro into the third ventricle, and extends along the iter a tertio (aqueduct of Sylvius) into the fourth ventricle; at the bottom of the iter ad infundibulum it ends in a cul-de-sac.

The Optic Tracts (Figs. 415, 443).—These are two well-marked flattened bundles of fibres which lie along the upper parts of the crustae. They are attached only by their upper edges, which also serve to mark the transition between upper limit of crusta and internal capsule of hemisphere. These edges also mark the limit of separation, without tearing, between the temporo-sphenoidal lobes of the hemispheres, which, at the base of the brain, overlap the optic tracts and the crustae. Each tract was originally a hollow outgrowth (optic vesicle) from the back part of the fore-brain. Anteriorly each unites with the other to form the optic commissure. The fibres of each are described in connection with the optic nerve (which see).

THE HEMISPHERES.

General Considerations and Development.

The two hemispheres are by far the largest portion of the encephalon, each one in bulk exceeding somewhat all the other divisions of the brain. Together with the fore part of the third ventricle they form what is called by some writers the prosencephalon or fore-brain.

Each hemisphere is an enormously developed "hemisphere vesicle" whose cavity is the lateral ventricle, and whose walls, originally smooth, thin, and spherical, are convoluted, elongated in various directions, and, for the most part, exceedingly thick. Although the two hemispheres in the adult brain are connected with each other by means of the corpus callosum and anterior commissure, this connection is merely between the adjacent walls, and in no wise involves the cavities, each cavity being as distinct from the opposite one as it is in early fetal life before the internital connection is established. Each lateral ventricle is, therefore, a complete cavity, communicating only with the third ventricle through the corresponding foramen of Monro.

The development of each hemisphere vesicle may be described approximately as follows (Figs. 412, 413, 414): After becoming a rounded hollow projection from the side of the prosencephalon, each hemisphere vesicle expands in an anterior direction and approaches close to its fellow. At the same time it grows upward over the inter-brain and backward along its side, while from this latter portion two projections may be said to take place—one still farther backward, covering over the dorsal surface of the mid-brain and cerebellum; and the other, downward and forward, overlapping somewhat the external surface of the portion from which it is derived, until its lower end projects below, and also overlaps the ventral surface of the mid-brain (crustae). We can thus distinguish four main divisions of the developing hemisphere vesicle: an anterior, a superior, the latter
giving off an inferior, and a posterior division. As these four divisions represent sufficiently accurately the four large divisions or lobes of the adult hemisphere, it will be more convenient, in tracing their further development, to give them the same names, thus: the anterior division will be called the frontal lobe; the superior, the parietal lobe; the posterior, the occipital lobe; and the inferior, the temporal or temporo-sphenoidal lobe. Each of these has its portion of the original cavity, all of which naturally intercommunicate.

The frontal lobes are now closely approximated in front of the inter-brain, while there is also to be noted the formation of the optic thalami, which are merely the thickened sides of the inter-brain (prosencephalon and thalamencephalon).

The parietal lobes are similarly approximated above the optic thalami, but they have now enlarged, so that the inner aspect of each comprises two regions (see Fig. 459)—one, just mentioned, close to its fellow above the inter-brain; the other, lower region, lying external to the external surface of the optic thalamus. Furthermore, the upper region is the inner wall of the cavity of the parietal lobe, which also comes above the inter-brain, while the lower region is simply the inner aspect of solid matter—i. e. a downward thickening of the original wall. Along the floor of that portion of the ventricle contained in the parietal lobe is now seen a thickening which soon resolves itself into a bundle of fibres. This band of fibres, when traced forward, is found to be continuous with a similar thickening around the foramen of Monro, which in its turn is continued down through the optic thalamus (anterior pillar of fornix; see page 761). The curve of this band is due to the marked antero-posterior flexure of the entire fetal brain which has already taken place, while its transition in position—i. e. to the floor of the "parietal cavity"—is due to a certain twisting or rotation which the hemisphere vesicle now undergoes.

The approximation of the parietal lobes brings these bands very close together as they curve upward, and, as neither one is developed in the cavity of the corresponding frontal lobe, each serves, just here, as a line of demarkation between the inner wall of the frontal lobe in front and that of the parietal lobe behind. Traced backward, these bands are necessarily found to lie dorsal to the inter-brain, since each is in the floor of the corresponding cavity of the parietal lobe.

Fornix.—The next point to be noted is the absolute approximation of the two frontal and of the "upper regions" of the inner aspects of the two parietal lobes. As a result of the latter approximation, the two anterior pillars of the fornix, just above the foramen of Monro, are brought together edge to edge, and an actual union takes place between them. This union extends posteriorly for more than half the length of the floor of each cavity of the parietal lobe, and is known as the body of the fornix, or as "the fornix" in the adult brain. The anterior pillars, however, as they curve downward, are not united, this slight separation persisting in the adult brain.

Anterior Commissure.—Immediately anterior to and connected with each of these pillars, just previous to its passage through the optic thalamus, is a portion of the inner wall of the cavity of the frontal lobe, which is now in close contact with the opposite one. Just at this point there now occurs an interchange of fibres between the inner walls of each frontal cavity. These fibres (anterior commissure) run transversely across the front of the upper part of the anterior boundary of the prosencephalon, and causes an absorption of its tissue, its epithelial lining excepted, so that the latter comes to lie directly on the centre part of the posterior aspect of the anterior commissure, in the interval between the anterior pillars of the fornix.

The lower part of the anterior boundary of the prosencephalon persists in the adult brain as the upper limit of the lamina cinerea (lamina terminalis).

Corpus Callosum.—The frontal lobes having now grown well forward, and having also curved upward to form the parietal lobes, and the inner surface of each frontal and the "upper region" of the inner surface of the corresponding parietal lobe having met the same structures of the opposite hemisphere, there is formed
a curved line of actual contact, all along which occurs an interchange of fibres running transversely from one hemisphere to the other. Another factor, besides the upward curve of the parietal lobe, in causing this line of contact to be curved is doubtless the antero-posterior flexure of the whole foetal brain, already referred to. This large transverse commissure, thus formed, curved anteriorly, is the corpus callosum of the adult brain.

This curved line, along which the above-mentioned interchange of fibres takes place, has two extremities, an anterior and a posterior.

The anterior extremity is immediately in front of, and in direct contact with, the lateral part of the anterior commissure. Here the corpus callosum itself is thin and conceals the anterior commissure from in front and below; it is also adherent to it and blends inferiorly with the lamina terminalis.

The posterior extremity of the curved line is at the posterior part of the inner wall of the cavity of the parietal lobe. Here the corpus callosum itself is very thick and with a free posterior edge, beyond which project, posteriorly, the inner surfaces of the occipital lobes, entirely separate from each other.

This curved line—or the cut surface of the corpus callosum, which is the same thing—will now be traced from the posterior to the anterior extremity.

As it passes along anteriorly in the inner wall of the “parietal cavity” it is quite near the floor, so that it soon reaches and becomes adherent to the corresponding half of the “body of the fornix” immediately below it. As it goes forward from this point it separates from its half of the fornix, which is now curving around the foramen of Monro. Continuing forward, the cut edge of the corpus callosum is now on the inner wall of the “frontal cavity.” It continues this course for a distance, and then bends sharply downward, after which it runs backward until it reaches the anterior commissure, by which it is separated from the anterior pillar of the fornix, just as the latter is about to run downward through the optic thalamus.

Septum Lucidum.—There is thus formed a somewhat oval-shaped interval, tapering posteriorly, bounded above and in front by the corpus callosum; below, by the corpus callosum (reflected part) and anterior commissure; behind and below, by the anterior pillar of the fornix and body of the fornix, respectively.

This interval is filled in by a lamina on each side, which is a portion of the inner walls of both frontal and parietal cavities. This lamina is necessarily in close contact with the opposite one, and they both together constitute the septum lucidum of the adult brain (Figs. 448, 461).

The corpus callosum in addition to forming the commissure just described spreads outwardly, also, in the frontal and parietal lobes, and, as it is now quite thick, its under surface forms the roof of the “parietal and frontal cavities;” its posterior surface (at the bend) is the anterior boundary of the “frontal cavity,” while the upper surface of its reflected portion is the floor of the frontal cavity.

Along the outer wall of both frontal and parietal cavities the corpus striatum is developed as a marked thickening, and close above it passes the corpus callosum. All portions of the frontal and parietal lobes external to the corpus striatum and above the corpus callosum, and those portions of the frontal lobe anterior to and below the corpus callosum, develop into thick, solid matter and project for a considerable distance, but without uniting with the opposite side, beyond the corpus callosum in the corresponding directions. This solid matter constitutes the bulk of the lobe.

The “lower region” of the internal surface of the parietal lobe (internal capsule of adult brain) is eventually closely united to the external surface of the optic thalamus (Figs. 461, 460).

The occipital lobe is the backward extension of the hemisphere. It is entirely separate from the opposite one. Its cavity is roofed over by backward curved prolongations from the corpus callosum.

The temporal lobe (temporo-sphenoidal) grows downward and forward, as
already described. It carries with it, in its floor, a prolongation of its corresponding half of the fornix, which, consequently, in the adult brain, is described as dividing posteriorly into its two posterior pillars. As this lobe curves downward it embraces, but does not adhere to, the pulvinar of the optic thalamus.

In the foetal brain a wide shallow cleft (Fig. 444) lies between the temporal and portions of the frontal and parietal lobes, but this deepens and narrows (fissure of Sylvius) as the lobe develops. The cavity of the temporal lobe lies close to its inner aspect, the bulk of the lobe developing externally. A portion of the corpus callosum roofs over the beginning of the temporal cavity.

The Lateral Ventricles, and Structures in Connection therewith.

The lateral ventricles are the cavities of the hemispheres, each being distinct from the other. In each hemisphere the lateral ventricle is situated in its lower and inner regions, being surrounded above, in front and externally, by the solid, chiefly white, matter of the hemisphere. Each lateral ventricle communicates through the foramen of Monro with the third ventricle, and is lined by a thin diaphanous membrane (the ependyma), covered by nucleated epithelium with cilia, scattered here and there in patches. It is moistened by a serous fluid, which is sometimes, even in health, secreted in considerable quantity. Each is separated from the other by a vertical septum, the septum lucidum.

Each lateral ventricle consists (Fig. 445) of a central cavity, or body, and three accessory cavities or cornua. The anterior cornu curves forward and outward into the substance of the frontal lobe. It comprises that portion of the ventricle which is anterior to the foramen of Monro. The body comprises that portion of the ventricle which lies between the foramen of Monro and the posterior part of the corpus callosum. It is situated low down in the parietal lobe. From its posterior extremity diverge the two following: The posterior cornu, called the digital cavity, curves backward into the occipital lobe; the middle cornu descends into the temporal lobe.

If the upper part of both hemispheres is removed, about half an inch above the level of the corpus callosum, the internal white matter will be exposed. It is an oval-shaped centre, of white substance, surrounded on all sides by a narrow convoluted margin of gray matter, which presents an equal thickness in nearly every part. This white central mass has been called the centrum ovale minus. Its surface is studded with numerous minute red dots (puncta vascu-
losa), produced by the escape of blood from divided blood-vessels. In inflammation or great congestion of the brain these are very numerous and of a dark color. If the remaining portion of one hemisphere is slightly separated from the other, a broad band of white substance will be observed connecting them at the bottom of the longitudinal fissure; this is the corpus callosum. The margins of the hemispheres which overlap this portion of the brain are called the labia cerebri. Each labium is part of the convolution of the corpus callosum (gyrus fonicatus), and the space between it and the upper surface of the corpus callosum has been termed the ventricle of the corpus callosum (Fig. 446).

The hemispheres should now be sliced off to a level with the corpus callosum, when the white substance of that structure will be seen connecting the two hemispheres. The large expanse of medullary matter now exposed, surrounded by the convoluted margin of gray substance, is called the centrum ovale majus of VIEUSSENS.

The corpus callosum (Figs. 442, 446) is a thick stratum of transverse fibres exposed at the bottom of the longitudinal fissure. It connects the two hemi-
lobe, where they meet the outer olfactory roots. They are called the peduncles of the corpus callosum. Posteriorly, the corpus callosum forms a thick rounded fold, called the splenium or pad, which is free for a little distance as it curves forward, and is then continuous with the fornix below. On its upper surface the structure of the corpus callosum is very apparent, being collected into coarse transverse bundles. Along the middle line is a linear depression, the raphe, bounded laterally by two or more slightly elevated longitudinal bands, called the striae longitudinales or nerves of Lancisi; and, still more externally, other longitudinal striæ are seen beneath the convolutions which rest on the corpus callosum. These are the striae longitudinales laterales or tectae. The under surface of the corpus callosum is continuous behind with the fornix, being separated from it in front by the septum lucidum, which forms a vertical partition between the two ventricles. On each side the fibres of the corpus callosum extend into the substance of the hemispheres, connecting them together. The greater thickness of the two extremities of this commissure is explained by the fact that the fibres from the anterior and posterior parts of each hemisphere do not pass directly across, but take a curved direction. The peduncles of the corpus callosum may be traced upward around the genu to become continuous with the striae longitudinales, or nerves of Lancisi, on the upper surface of the corpus callosum.

The fibres from the splenium, which curve backward to roof in the posterior cornu are known as the forcepts major; those from just above the genu, which curve forward to roof in the front part of the anterior cornu constitute the forcepts minor; while the term tapetum is given to the main body of the fibres.

The central cavity, or body, of the lateral ventricle is comparatively wide, but is a mere slit as regards its perpendicular diameter. It is (Fig. 447) bounded, above, by the under surface of the corpus callosum, which forms the roof of the cavity. Internally is a vertical partition, the posterior portion of the septum lucidum, which separates it from the opposite ventricle, and connects the under surface of the corpus callosum with the fornix. Its floor is formed by the following parts, enumerated in their order of position from without inward: the

![Diagram of the brain](image-url)
corpus striatum (caudate nucleus), tênia semicircularis, optic thalamus, choroid plexus, one-half of body of fornix, and corresponding posterior pillar.

The anterior cornu is deep and narrow, passing outward into the frontal lobe and curving round the anterior extremity of the corpus striatum. Its apex points outward. It is bounded, above, by the corpus callosum; externally, by the corpus striatum (head of caudate nucleus); in front, by the posterior surface of the genu of the corpus callosum; internally, by the anterior or broad portion of the septum lucidum; inferiorly, by the upper surface of the rostrum (each side of its middle line) of the corpus callosum. This last is the floor of the cornu, and is exceedingly narrow, the outer wall, convex toward the cavity, almost meeting the lower part of the septum lucidum below (Figs. 448 and 449).

The posterior cornu, or digital cavity (Fig. 445), curves backward into the substance of the occipital lobe, its direction being backward and outward, and then inward. On its inner wall is seen a longitudinal eminence which is produced by the extension inward of the calcarine sulcus; this is called the hippocampus minor, or calcar avis. Just above this is a smaller projection, bulb of the posterior horn (Fig. 456), caused by the bulging of the fibres of the forceps major of the corpus callosum.

Between the middle and posterior horns a smooth triangular surface is observed. It is called the trigonum ventriculi.

The middle or descending cornu, the longest of the three (Fig. 445), traverses the temporal lobe of the brain, forming in its course a remarkable curve round the back of the optic thalamus (pulvinar). It passes, at first, backward, outward, and downward, and then curves round the crus of forward and inward, nearly to the apex of the middle lobe, close to the fissure of Sylvius. Its upper boundary, or roof, is formed by the under surface of the corpus callosum, the small portion of the pulvinar of the optic thalamus covered by epithelium, and by the white matter (internal capsule) of the temporal lobe, with which are incorporated the reflected parts of the nucleus caudatus of the corpus striatum and tênia semicircularis, which are prolonged into it. Its lower boundary, or
floor, presents for examination the following parts: the hippocampus major, pes hippocampi, eminentia collateralis or pes accessorius, and corpus fimbriatum from the fornix. The outer wall is white matter of the temporal lobe. The inner wall is a layer of epithelium, prolonged from that covering the pulvinar, just mentioned, which is invaginated by a fold of pia mater, and thus is formed the choroid plexus.

The corpus striatum (Fig. 450) has received its name from the striped appearance which its section presents, in consequence of diverging white fibres being mixed with the gray matter which forms the greater part of its substance. The greater portion of this body is imbedded in the white substance of the hemisphere, and is therefore external to the ventricle. It is termed the extraventricular por-

![Diagram of the brain](image)

Fig. 450.—Middle part of a horizontal section through the cerebrum at the level of the dotted line in the small figure of one hemisphere. (From Ellis, after Dalton).

tion, or the nucleus lenticularis: a part, however, is visible in the ventricle and its anterior cornu; this is the intraventricular portion, or the nucleus caudatus. The intraventricular portion is a pear-shaped mass of gray matter; its broad anterior extremity is the convex outer wall of the anterior cornu. Its narrow end is directed backward, and lies on the outer part of the floor of the body of the ventricle. It is continued, by a sharp anterior bend, into the roof of the descending cornu; it is covered by the lining of the cavity and crossed by some veins of considerable size. It is separated from the extraventricular portion by a lamina of white matter, the internal capsule, in contradistinction to a lamina of white matter which covers the outer surface of the extraventricular portion of the corpus striatum, and which is called the external capsule.

The extraventricular portion of the corpus striatum, or nucleus lenticularis, is oval in form. It does not extend as far forward or backward as the nucleus
caudatus. It is bounded externally by a lamina of white matter called the external capsule, which is covered on its outer surface by a thin layer of gray matter termed the claustrum. The claustrum presents ridges and furrows on its outer surface, corresponding to the convolutions and sulci of the island of Reil, with the white matter of which it is in immediate relation.

Antero-inferiorly the ends of the two nuclei of the corpus striatum are united by a thin gray lamina which appears at the base of the brain in the anterior perforated space. The caudate nucleus terminates, after running downward and forward in the roof of the descending cornu, in the nucleus amygdalae, a collection of gray matter in the apex of the temporal lobe. The base of the claustrum is also in connection with this nucleus.

The gray matter (Fig. 449) of the corpus striatum is permeated by tracts of medullated nerve-fibres, some of which probably originate in it. The nerve-cells are multipolar, both large and small, the larger being principally found in the lenticular nucleus.

On section, the substance of the corpus striatum appears of reddish-gray color. On a transverse vertical section, the lenticular nucleus shows two lamina of white matter parallel with its outer surface, forming three areas of gray matter, the two inner of which are known as the globus pallidus, the outer as the putamen (Fig. 447). The fibres of the nucleus enter and leave it, the former chiefly derived from the ansa lenticularis (see page 747), the latter proceeding into the internal capsule and corona radiata, which last is made up of the radiating diverging fibres of the upward prolongation of the internal capsule which extend to the cortex.

The internal capsule is formed by fibres of the crista of the crus cerebri, supplemented by fibres derived from the optic thalamus and corpus striatum on each side. In horizontal section it is seen to be somewhat abruptly curved, with its convexity inward; the prominence of the curve is called the genu, and projects between the intraventricular portion of the corpus striatum and the optic thalamus (Figs. 447, 448, 450). In front of the genu the internal capsule separates the two portions of the corpus striatum; behind, it lies between the optic thalamus and lenticular nucleus. The portions of the internal capsule, anterior and posterior to the genu, are known, respectively, as the anterior and posterior segments. The fibres of the former proceed to the prefrontal region of the cortex; of the latter, to the occipito-temporal region; while those of the middle third go to the Rolando\'s region (motor) of the cortex. Other fibres, in the internal capsule, than those of the crista are derived from the nuclei of the corpus striatum, the optic thalamus, the subthalamic tegmental region, and from the cortex of the opposite side through the corpus callosum (see also page 785).

The tenia semicircularis (Figs. 445, 447, and 461) is a narrow, whitish band of medullary substance situated in the depression between the nucleus caudatus and optic thalamus. Anteriorly, it descends, between the head of the caudate nucleus and the anterior extremity of the optic thalamus, to join the anterior pillar of the fornix, below the level of the foramen of Monro, where most of the fibres continue with those of the pillar, while the remainder pass over the anterior commissure and terminate in the gray matter of the anterior perforated space. Behind, it is continued into the roof of the middle or descending horn of the lateral ventricle, lying parallel with the caudate nucleus, to enter, with it, the nucleus amygdalae. Beneath it is a large vein (vena corporis striati), which receives numerous small veins from the surface of the corpus striatum and optic thalamus, and joins the vena Galeni. On transverse vertical section the tenia is seen to lie upon a projection from the internal capsule.

The fornix (Figs. 442, 447, 451) is a longitudinal band of white matter situated beneath the corpus callosum, with which it is continuous behind, but separated from it in front by the septum lucidum. It may be described as consisting of two symmetrical halves, one for each hemisphere. These two portions are joined together in the middle line (along which is attached the lower edge of the
septum lucidum), where they form the body, but are separated from one another in front and behind, forming the anterior and posterior pillars, or columnae formicis and crura formicis, respectively.

The body of the fornix is triangular; narrow in front, broad behind. Its upper surface is connected, in the median line, to the septum lucidum in front and the corpus callosum behind, while laterally this surface forms part of the floor of the body of each lateral ventricle. Its under surface rests upon the velum interpositum, which separates it from the third ventricle and from the inner portion of the superior surfaces of the optic thalamus. Its free outer edge, on each side, is in contact with the choroid plexus, which projects from under it. This edge, running from behind forward and inward, rests in the groove already referred to, having a similar direction, on the superior surface of the thalamus, but with a portion of the velum interpositum, of course, separating it from the groove.

The anterior pillars are rounded bundles which arch downward toward the base of the brain, separated from each other by a narrow interval, and each descends through the anterior portion of the optic thalamus. Each is placed immediately behind the anterior commissure. At the base of the brain the white fibres of each pillar make a sudden curve and form the outer part of the corresponding corpus albicans (see page 759), from which point they may be traced upward into the substance of the corresponding optic thalamus. The anterior pillars of the fornix are connected in their course with the peduncles of the pineal gland and the superficial fibres of the tectum semicircularis, and receive fibres from the septum lucidum.

Between the anterior pillars of the fornix and the anterior extremities of the optic thalami an oval aperture is seen on each side: this is the foramen of Monro (Fig. 442). The two openings descend toward the middle line and lead into the upper part of the third ventricle. Through these openings the lateral ventricles on each side communicate with the third ventricle, and consequently with each other. Its boundaries are, therefore, in front, the anterior pillars of the fornix; behind, the anterior extremity of the optic thalamus; above, the body of the fornix; and below, the junction between the anterior pillars of the fornix and the optic thalamus.

The posterior pillars are flattened bands, and at their commencement are intimately connected by their upper surfaces with the corpus callosum; diverging from one another, each passes downward around and behind the pulvinar of the

Fig. 451.—Transverse vertical section of brain behind the middle commissure. The cut-surface looks backward, × 4. (Gegenbaur.)
optic thalamus, and then along the floor of the descending horn of the lateral ventricle, where some of its fibres blend with the white matter of the hippocampus major, while the remainder are prolonged along its inner border as the corpus fimbriatum (Figs. 445, 454), which extends into the white matter of the uncus of the hippocampal gyrus. Upon examining the under surface of the fornix, between its diverging posterior pillars a triangular portion of the under surface of the corpus callosum may be seen, the base of which is the splenium. On it are a number of lines, some transverse, others longitudinal or oblique. This portion has been termed the lyra, from the fancied resemblance it bears to the strings of a harp (Fig. 452). The corpus fimbriatum is often called the fimbria.

The anterior commissure is a round bundle of white fibres placed in front of the anterior pillars of the fornix, and appears to connect together the corpora striata. It passes outward through the corpus striatum on each side, and then curves backward into the substance of the temporal lobe.

The septum lucidum (or pellucidum) (Figs. 446, 449) forms the internal boundary of the body and anterior cornu of the lateral ventricle. It is a thin septum attached, above, to the under surface of the corpus callosum; below, to the anterior part of the fornix, and in front of this to the reflected portion of the corpus callosum and anterior commissure; behind, to the anterior pillars of the fornix; in front, to the posterior surface of genu of the corpus callosum. It is broad in front, and narrow behind, its external surfaces looking toward the cavities of the ventricles. The septum consists of two laminae, separated by a narrow interval, the fifth ventricle.
Fifth Ventricle.—The fifth ventricle was originally a part of the great longitudinal fissure which separated the two hemisphere vesicles, but has become shut off by the union of the hemispheres in the formation of the corpus callosum and the fornix. Its walls are therefore formed by the median wall of the hemispheres, and each consists of an internal layer of gray matter derived from the gray matter of the cortex and an external layer of white substance continuous with the white matter of the cerebral hemispheres. This is lined on its external surface by the ependyma of the corresponding lateral ventricle. The fifth ventricle is not lined by epithelium, but by a delicate layer of modified pia mater. It has no connection with any of the “regular” ventricles.

The structures of the floor of the descending cornu will now be considered.

The hippocampus major, or cornu Ammonis (Figs. 445, 452, 456), so called from its resemblance to a ram’s horn, is a white eminence, of a curved elongated form, extending throughout the entire length of the floor of the middle horn of the lateral ventricle. At its lower extremity it becomes enlarged, and presents a number of rounded elevations with intervening depressions, which, from presenting some resemblance to the paw of an animal, is called the pes hippocampi. If a transverse section is made through the hippocampus major (Fig. 455), it will be seen that this eminence is produced by the extension inward of the dentate (hippocampal) fissure on the mesial aspect of the temporal lobe. This fissure, like all the other fissures of the hemisphere, is lined by a dipping in and out again of the gray cortex; but, whereas in these fissures the gray lining, after coming out, is continuous with that of an adjacent fissure, the gray lining of the hippocampal fissure, after turning on itself, comes out and terminates in a free edge, forming a notched ridge, the fascia dentata (Figs. 453, 454). The hippocampus is covered on its ventricular surface by the lining membrane of the ventricle, beneath which is a thin lamina of white matter (alveus), which is continuous with the corpus fimbriatum of the fornix, and beneath this is the “gray matter” of the hippocampus—i.e. the cortical lining of the hippocampal fissure, just described. This gray matter is seen, on cross-section, to make a secondary turn which embraces a slender process of white matter derived from the white lamina before it emerges as the free edge.

The corpus fimbriatum (Figs. 445, 454, 456) (terania hippocampi) is a narrow white band situated immediately below the choroid plexus. It is the thin prolongation of the posterior pillar of the fornix, and is attached by its inner margin.
along the curved inner border of the hippocampus major as it descends into the middle horn of the lateral ventricle. It may be traced as far as the crochet or hook
of the hippocampal convolution. Its outer edge is free, and lies on the surface of the hippocampus. This edge is directed toward the cavity of the descending cornu.

The eminentia collateralis (Fig. 453), or pes accessorius, is a white eminence, varying in size, placed between the hippocampus major and the outer wall of the cornu. It is formed by the protrusion inward of the collateral fissure.

Fascia Dentata (Figs. 453, 454, 456).—On separating the inner border of the corpus fimbriatum from the choroid plexus, and raising the edge of the former, a serrated band of gray substance, the edge of the gray substance in the dentate or hippocampal fissure, will be seen beneath it: this is the fascia dentata. Correctly speaking, it is not placed within the cavity of the descending cornu. The fascia dentata has a curved direction, following the course of the hippocampus, and also runs obliquely from above downward and forward. Its lower extremity is lost in the gray matter of the uncus or hook of the hippocampal gyrus, where it is seen as a small band (Giacomini) passing transversely over the hook. Its upper extremity is well marked (fasciola cinerea), and lies immediately behind and below the splenium of the corpus callosum, over and above which it is continuous with the lateral and mesial longitudinal striae of that body (Fig. 455).
The choroid plexuses (Figs. 457, 458) of each lateral ventricle are two in number, one in the floor of the body, and the other in the descending cornu. Each is a vascular fringe-like membrane with a free edge looking toward the ventricular cavity, and an attached margin which is continuous with two layers of pia mater.

The choroid plexus of the body of the ventricle is, as before stated, the thickened, convoluted side of the velum interpositum, which is made up of two layers of pia mater. The reasons for the presence of two layers in the velum interpositum, as well as for their continuity with one another at their free margins, and for the fact of the existence of such free margins, must be sought for in the method of development.

In the brief account given of the development of the hemisphere vesicles no mention was made of the pia mater. But it must be understood, of course, that the pia mater covers the entire brain-tube, and takes part in, and adapts itself to, all the different changes in shape and position which the various portions of the brain undergo.

We thus have, at a certain point of development, three "tubes" of pia mater—one encircling the inter-brain, and one investing each hemisphere vesicle (see Fig. 459). As the latter approaches its fellow it also grows in toward the inter-brain. Finally, as already described, actual adhesions take place between the mesial aspects of each hemisphere above the inter-brain, and between that portion of the hemisphere which lies external to the inter-brain and the side of the inter-brain (optic thalami); while the under surfaces of the hemispheres (corpus callosum and fornix) merely rest on, and are not adherent to, the superior surface of the inter-brain. The effect on the pia mater (see Figs. 460, 461) mesially and
THE BRAIN AND ITS MEMBRANES.

above the inter-brain, is thus clear: (1) The pia lining the mesial aspect of each hemisphere is absorbed by the formation of the corpus callosum and the coming together of the two halves of the fornix; hence (2), the part above the corpus callosum becomes continuous with that of the other side across the upper surface of the corpus callosum; while (3) the pia on the under surface of each hemisphere (below the corpus callosum and fornix) becomes continuous with that on the under surface of the other, and forms one layer from side to side (upper layer of velum interpositum). This upper layer of the velum interpositum is now in close contact with the layer of the pia covering the superior surface of the inter-brain (lower layer of the velum interpositum), but they are not absorbed, because no adhesions take place between the corresponding portions of the brain.

On the sides the effect of the adhesion between the hemisphere and the optic thalamus is to cause absorption of the layer of pia mater covering each;

![Diagram](image)

hence, as the pia mater on the hemisphere is originally continuous with the upper layer of the velum interpositum, and the pia mater on the outer side of the optic thalamus with the lower layer of the same, it follows that the two layers become continuous at their margins or along the line where each is "cut off," as it were, from its original prolongation (Figs. 460, 461).

This margin is at first along the border between the superior and external surface of the thalamus, but soon becomes shifted mesially, so that it comes to lie along the groove on the superior surface of the thalamus. This shifting is due to the absorption of the pia-mater layers external to the groove, caused by the adhesion which has taken place between the subjacent portion of the thalamus and the superjacent portion (epithelial floor, see below) of the hemisphere.

The anterior extremity of the velum interpositum, narrow and bifid, as already described, is necessarily limited by the curve of the anterior pillars of the fornix, behind which the two layers are continuous, because it is at and around this point, which might be regarded as a sort of hinge, that the hemispheres swing up and over the inter-brain, carrying with them each one half of the future upper layer of the velum interpositum.
Epithelial Floor of the Body of the Ventricle.—The margin of the velum interpositum thus formed is necessarily situated between the under surface of the floor of the body of lateral ventricle above and the upper surface of optic thalamus below, but it does not reach out over all of this surface, but lies only on its inner half, as already explained. Hence a portion of the under surface of the floor of the ventricle must rest on the outer half of the upper surface of the thalamus. Now, this portion of the floor, together with that immediately superjacent to the margin of the velum interpositum, becomes reduced to a layer of epithelium which stretches from the edge of the fornix over to the tecta semicircularis. This epithelium is continuous with that lining the ventricle both at the edge of the fornix and at the tecta. As it passes over the fringe-like margin of the velum interpositum it invests all its processes, and thus forms the true choroid plexus. As it passes over the optic thalamus it has ependyma beneath it, as also where it covers tecta semicircularis, caudate nucleus, under surface of corpus callosum, ventricular aspect of septum lucidum, and upper surface of corresponding half of fornix.

Epithelial Inner Wall of Descending Cornu.—The entire inner wall of this cornu is reduced to a layer of epithelium. It is, morphologically, the continuation of the epithelium forming part of the floor of the body of the ventricle just described, and it stretches between the same structures, or rather their prolongations — i.e. tecta semicircularis in roof of septum lucidum in floor (Figs. 460 and 461). In the region of transition from body to descending cornu, just at the curve, the epithelium curves downward also, and stretches, now, between edge of posterior pillar of fornix (posterior part) across, on the rounded pulvinar of the optic thalamus, to the curved part of the tecta, which is immediately external to and lies against the outer aspect of the pulvinar. Hence this part of the epithelium is, strictly speaking, a portion of the roof of the descending cornu (see p. 758). Just beyond this point the epithelium assumes the mesial position and becomes the regular inner wall of the cornu.
Choroid Plexus of Descending Cornu.—The epithelial inner wall, just described, is invaginated by and closely invests a fringe-like margin of pia mater (Fig. 461), which apparently passes into the ventricle, turns on itself, and passes out again, but is everywhere covered, toward the cavity of the cornu, by the latter's now greatly convoluted inner epithelial wall. This is the choroid plexus of the descending cornu, and when seen from above it lies over the hippocampus major and conceals it from view, as well as the corpus fimbriatum.

The two layers of pia mater, of which the margins, covered by epithelium, make up the choroid plexus, are in continuity with the two layers of the velum interpositum, whose margins, also covered by epithelium, form the choroid plexuses of the bodies of the ventricles. But the upper layer of the velum is continuous with the lower layer of the choroid plexus of the cornu, and, vice versâ, this relation being due to the bending downward, forward, and inward of the temporal lobe and the descending cornu. This relation may perhaps be better appreciated by tracing these layers separately, thus:

The lower layer of the "choroid plexus" of the descending cornu, if traced out of the cornu—i. e. toward the median line—passes, at its lower part, right around the under surface of the temporal lobe; if traced at its upper part—i. e. at the curve of junction between this cornu and body of ventricle—this same layer will be found to bend sharply forward on itself and to come forward under the edge of the now superiorly placed fornix, and be continuous with the upper layer of the velum. Posteriorly and externally, this layer is in continuity with the pia mater covering the under surfaces of the occipital and temporal lobes.

The upper layer of the "choroid plexus" of the descending cornu, if traced in the same manner—i. e. at two levels—is found, at the lower level, to be continuous with the pia mater covering the crustæ of the mid-brain; at the upper level it also bends sharply forward, comes forward under the fornix, and is con-
tinued into the lower layer of the velum interpositum. Just at the forward bend this layer is really anterior to the other one. Posteriorly, this same layer is in continuity with the pia mater covering the corpora quadrigemina, which, in its turn, if traced ventrally, is seen to be continuous with that already mentioned covering the crusae.

It would appear, then, from the foregoing, that this whole arrangement of pia mater is a complicated invagination or tucking-in process of an originally single layer. Morphologically, however, we find this arrangement to be caused by the absorption of the contiguous layers of the three "tubes" of pia mater already referred to. Thus (cf. Figs. 459, 460, 461), the pia mater covering the crusae should be considered, as it really does in an early stage of development, as running up on the outer side of, and around and behind the pulvinar of, the optic thalamus to its upper surface, and thence inward to pass into continuity with the lower layer of the velum interpositum, thus making one tube; while, similarly, the upper layer of the pia from the choroid plexus of the descending cornu should be considered, not as being reflected mesially on to the crusae, but as running upward along the inner aspect of the internal capsule to the tenia semicircularis, and thence inward along the under surface of the floor of the body of the ventricle to join with the upper layer of the velum interpositum, which, in its turn, should be considered as splitting along its middle line, each half to bend upward, lying mesial to the corresponding half of the fornix, septum lucidum, and corpus callosum, to meet the corresponding layer of pia mater lining the mesial aspect of the hemisphere above the corpus callosum; thus forming two tubes.

At the junction between the choroid plexus of the body and that of the descending cornu in the adult brain there is a twisting backward of the latter, so that its free edge is directed posteriorly, while that of the former looks antero-externally (Fig. 457). It may sometimes look mesially, bending over the fornix.

Structure of Choroid Plexus.—The plexus consists of minute and highly vascular villous processes, composed of large round corpuscles, containing, besides a central nucleus, several yellowish granules and fat-molecules, and covered by a single layer of flattened epithelium. The arteries of the choroid plexus enter along the descending cornu, and, after ramifying through its substance, send branches into the substance of the brain. A constant branch, the anterior choroid, enters at the extremity of the middle horn of the lateral ventricle, and supplies the velum interpositum and the choroid plexus. The veins of the choroid plexus terminate in the vena Galeni.

The Transverse Fissure (Fig. 454).—The descending cornu is a mere cleft; that is, its roof and floor are very close together. Hence the tenia semicircularis of the roof, which runs along in the substance of the white matter of the temporal lobe, this white matter being the outer and under aspect of the beginning of the internal capsule, is quite near the corpus fimbriatum in the floor. Between the two pass the two layers of the pia mater which form the choroid plexus. If this pia mater be pulled out, the epithelial inner wall will necessarily come with it, and a cleft-like orifice into the cornu be produced. A similar cleft above will be caused by removal of the velum interpositum and choroid plexuses of the bodies of the ventricles, and if the plexus of the other cornu be removed also, there will remain two large curved fissures, one on each side, extending from the end of the descending cornu to the corresponding foramen of Monro. Beginning at the foramen, the fissure will be bounded by edge of body and posterior pillar of fornix above, and upper surface of optic thalamus below (Fig. 462). At the curve of the descending cornu the cleft will lie between pulvinar of optic thalamus in front and edge of posterior pillar of fornix (now beginning to twist into its position in the floor of the descending cornu as corpus fimbriatum) behind; while along the cornu it is bounded below by corpus fimbriatum, and above by edge of white matter of temporal lobe, along which is running the tenia semicircularis. These two fissures, taken together, are known as the transverse fissure of the brain, and only exist when the pia mater and choroid plexuses are removed. Hence it
is not a real fissure or sulcus, but a rent in part of the floor of the body and in the inner wall of the descending cornu of the lateral ventricle. The cleft formed by removal of the plexus of the body of the ventricle leads mesially into a space whose upper boundary is the under surface of fornix and corpus callosum, the lower boundary being the upper surfaces of the optic thalami on each side, while in the middle part is seen the cavity of the third ventricle, which has necessarily been unroofed by the removal of the velum interpositum. Posteriorly, this space continues into the larger one separating splenium of corpus callosum above and pineal gland and corpora quadrigemina below; while in its turn this interval is prolonged posteriorly into the still larger interspace between under surfaces of occipital lobes and upper surface of cerebellum (Fig. 463).

The Surface Aspect of the Hemispheres.

Each hemisphere, as already stated, has four main lobes, frontal, parietal, temporal or temporo-sphenoidal, and occipital. The white substance or medullary centre of each of these lobes lies next to the corresponding portion of the ventricle, and is of course directly continuous with that of an adjacent lobe, so that, as far as the white matter is concerned, there is no actual demarkation between the lobes. The surfaces of these lobes, however, can be fairly accurately separated from each other; but, since they constitute, all taken together, the surface of the entire hemisphere, it is more convenient to consider this first, and it is to be remembered that the various "lobes" to be mentioned are really the surfaces of these lobes.

The surface of each hemisphere presents the following general points for consideration: Its under surface or base is of an irregular form, resting in front on the anterior and middle fosse of the skull, behind upon the tentorium cerebelli. There is a small portion of the under surface which is adherent. This is equal in width to the internal capsule, and is the line of junction between its fibres and those of the crista (see Fig. 460). Its upper surface is of an ovoid form, broader behind than in front, convex in its general outline, and separated from
that of its fellow by the *great longitudinal fissure*, which extends throughout the entire length of the cerebrum in the middle line, reaching down to the base of the brain in front and behind, but interrupted in the middle by a broad transverse commissure of white matter, the *corpus callosum*, which connects the two hemispheres together. This fissure lodges the falx cerebri, and indicates the original development of the hemispheres by two lateral halves.

Each hemisphere presents also an *outer surface*, which is convex to correspond with the vault of the cranium; an *inner surface*, which is flattened and in contact with the opposite hemisphere (the two inner surfaces forming the sides of the longitudinal fissure); that is, above, in front of, and below (reflected portion) corpus callosum; the *lower* part of the mesial surface (inner aspect of internal capsule) resting against and being adherent to outer side of optic thalamus (Fig. 461).

If the arachnoid and pia mater are removed, the entire surface of each hemisphere will be seen to present a number of depressions (*fissures* and *sulci*) separating a number of convoluted eminences (*convolutions* or *gyri*).

The depressions are of two kinds, *fissures* and *sulci*. The *fissures* are few in number; they are constant in their arrangement, and are produced by marked foldings of the hemisphere during the process of development. There are seven—fissure of Sylvius, fissure of Rolando, parieto-occipital, calloso-marginal, hippocampal, calcarine, and collateral fissures. The *first four* serve to mark off from each other the larger lobes of the hemisphere—*i.e.* frontal, parietal, temporal, and occipital—and also two others, the *island of Reil* or central lobe, and the *limbic lobe*. There is still one other lobe, the *olfactory*. The three last-named fissures cause elevations in the ventricle—*viz.* hippocampus major and minor and eminentia collateralis.

The *sulci* are much more numerous; they are depressions of the gray matter, which is folded inward and only indents the central white substance; they vary in different brains and in different parts of the same brain.
The terms "fissure" and "sulcus" are often used interchangeably.

The Gyri or Convolutions.—There is no accurate resemblance between the convolutions in different brains, nor are they exactly symmetrical on the two sides of the same brain, but their general arrangement or plan is fairly constant. Certain infoldings of the cerebrum take place at an early period of development and form important landmarks, which are constant and can without difficulty be recognized, but the secondary depressions and convolutions vary considerably.

The number and extent of the convolutions, as well as their depth, appear to bear a close relation to the intellectual power of the individual, as is shown in their increasing complexity of arrangement as we ascend from the lowest mammalia up to man. Thus they are absent in some of the lower orders of mammalia, and they increase in number and extent through the higher orders. In man they present the most complex arrangement. Again, in the child at birth, before the intellectual faculties are exercised, the convolutions have a very simple arrangement, presenting few undulations, and the sulci between them are less deep than in the adult.

The convolutions on the outer convex surface of the hemisphere are the largest and most complicated; their general direction is more or less oblique; they frequently branch like the letter Y in their course upward and backward toward the longitudinal fissure; these convolutions attain their greatest development in man, and are especially characteristic of the human brain.
Structure of the Convolutions.—The outer surface of each convolution, as well as the sides and bottom of the sulci between them, are composed of gray matter, which is here called the cortical substance. The interior of each convolution is composed of white matter, medullary centre, the white fibres of which blend with the gray matter not only on the surface of the gyrus, but at the sides and bottom of the sulci as well. By this arrangement the convolutions are adapted to increase the amount of gray matter without occupying much additional space, and to afford a greater extent of surface for the termination of the white fibres.

External Lobes and Fissures of the Hemisphere.—Each hemisphere of the brain on its external surface is divided into five lobes, the division being made by the main fissures and by imaginary lines drawn to connect them (Fig. 466).

The fissures dividing the five lobes on the external surface of the hemispheres are three in number, and are named fissure of Sylvius, fissure of Rolando, and parieto-occipital fissure.

The fissure of Sylvius separates the frontal from the temporal lobe, and lodges the middle cerebral artery. It begins, at the base of the brain, at the outer side of a depression at the bottom of which is the anterior perforated space. This depression is called the vallecula Sylvii. It then passes outward to the external surface of the hemisphere, and gives off a short anterior limb, which passes forward, and another, ascending limb, which passes upward into the inferior frontal convolution. It is then continued backward as the horizontal limb, and terminates in the parietal lobe after curving upward for a short distance. It separates the frontal and parietal lobes from the temporal, and occupies about the middle third of the lateral surface of the hemisphere.

The fissure of Rolando is situated about the middle of the outer surface of the hemisphere. It commences at or near the longitudinal fissure, and runs downward and forward to terminate a little above the beginning of the horizontal limb of the fissure of Sylvius, and about half an inch behind the ascending limb of the same fissure. It separates the frontal from the parietal lobe.

The parieto-occipital fissure is only seen to a slight extent on the outer surface of the hemisphere, and is not so distinctly marked as the others. The portion on the outer surface of the hemisphere is sometimes called the external parieto-occipital fissure, to distinguish it from the continuation of the sulcus on the internal surface of the hemisphere, which would then be termed the internal parieto-occipital fissure. It commences about midway between the posterior extremity of the
brain and the fissure of Rolando, and runs downward and forward for somewhat less than an inch. It separates the parietal and occipital lobes.

These three fissures divide the external surface of the hemisphere into five lobes—the frontal, the parietal, the occipital, the temporal, and the central or island of Reil.

The frontal lobe is that portion of the brain which is situated in front of the fissure of Rolando and above the horizontal limb of the fissure of Sylvius. Its under surface rests on the orbital plate of the frontal bone, and is termed the orbital lobe.

The outer surface of the frontal lobe presents three sulci, which divide it into four primary convolutions: 1. The precentral sulcus runs upward through this lobe, parallel to the fissure of Rolando. It may be interrupted by annectant gyri. It divides off a convolution which lies between it and the fissure of Rolando, and which is called the ascending frontal convolution. 2 and 3. From it two sulci, the superior and inferior frontal sulci, run forward and downward, and divide the remainder of the outer surface of the lobe—namely, that part in front of the precentral sulcus—into three principal convolutions, named, respectively, the superior, middle, and inferior frontal convolutions (or "lobes").

The under surface of the frontal lobe, which rests on the orbital plate of the frontal bone, is named the orbital lobe (Fig. 467). This surface of the frontal lobe is divided into three convolutions by a well-marked sulcus, the orbital sulcus. These are named, from their positions, the internal, anterior, and posterior orbital convolutions, and are the continuations respectively of the superior, middle, and inferior frontal convolutions. The internal orbital convolution presents or is subdivided by a well-marked groove or sulcus (olfactory sulcus) for the olfactory tract.

The ascending frontal convolution is a simple convolution, bounded in front by the precentral sulcus, behind by the fissure of Rolando, and extending from the...
upper margin of the hemisphere above to a little behind the bifurcation of the fissure of Sylvius below.

The *superior frontal convolution* is situated between the margin of the longitudinal fissure and the superior frontal sulcus. It extends above on to the inner aspect of the hemisphere, forming the marginal convolution, and in front and below on to the orbital surface, forming the internal orbital convolution. It is much divided by secondary sulci.

The *middle frontal convolution* is situated between the superior and inferior frontal sulci, and extends from the precentral sulcus to the lower margin of the lobe, where it forms the anterior orbital convolution.

The *inferior frontal convolution* is situated below the inferior frontal sulcus, and extends from the lower part of the precentral sulcus, circling round the ascending and anterior limbs of the fissure of Sylvius, to the under surface of the lobe, where it forms the posterior orbital convolution.

The *parietal lobe* is situated between the frontal and occipital lobes, and is not much more than half the size of the former. It is bounded in front by the fissure of Rolando; behind, by the external parieto-occipital fissure and a line drawn in continuation of that sulcus over the hemisphere; and below, by the horizontal limb of the fissure of Sylvius and a line connecting this with the lower end of the superior occipital sulcus. Above, it extends to the longitudinal fissure. It presents for examination two sulci and three convolutions.

The *intraparietal sulcus* commences close to the horizontal limb of the fissure of Sylvius, about midway between the fissure of Rolando and the upturned extremity of the fissure of Sylvius. It first runs upward parallel to and behind the lower half of the fissure of Rolando, and then turns backward, extending nearly to the termination of the external parieto-occipital fissure, where it sometimes becomes continuous with the superior occipital sulcus. The ascending portion of this sulcus separates off a convolution, the *ascending parietal*, which lies between it and the fissure of Rolando, whilst the horizontal portion divides the remainder of the parietal lobe into two other convolutions, the *superior* and *inferior parietal*.

The *post-central sulcus* is a slightly marked groove, which is sometimes a branch of the intraparietal sulcus, being given off where the ascending portion of this sulcus turns backward. It lies parallel to and behind the upper part of the fissure of Rolando, and separates the ascending from the superior parietal convolution.\(^1\)

\(^1\) Professor Cunningham describes these two sulci, intraparietal and post central, somewhat differently. He regards them as both belonging to the intraparietal sulcus, which he divides into three parts: the ascending portion of the intraparietal, as described above, he terms the *ramus verticalis superior*; the horizontal portion as the *ramus horizontalis*; while the post-central sulcus he denominates the *ramus verticalis superior*. He states that considerable variability is exhibited in the relation to each
The ascending parietal convolution is bounded in front by the fissure of Rolando, behind by the ascending portion of the intraparietal and the post-central sulci. It extends from the great longitudinal fissure above to the horizontal limb of the fissure of Sylvius below. It lies parallel with the ascending frontal convolution, with which it is connected below, and also generally above, the termination of the fissure of Rolando.

The superior parietal convolution is bounded in front by the post-central sulcus, which separates it from the previous convolution, but with which it is usually connected above the upper extremity of the sulcus; behind, it is bounded by the external parieto-occipital fissure, below the termination of which it is connected with the occipital lobe by a narrow convolution, the first annectant gyrus. Below, it is separated from the inferior parietal convolution by the horizontal portion of the intraparietal sulcus; and above it is continuous on the inner surface of the hemisphere with the quadrate lobe.

The inferior parietal convolution is that portion of the parietal lobe which is situated between the ascending portion of the intraparietal sulcus in front, the horizontal portion of the same sulcus above, the horizontal limb of the fissure of Sylvius below, and the posterior boundary of the parietal lobe behind. It is subdivided into two convolutions by an indistinct groove. One, the supramarginal, lies behind the lower end of the intraparietal sulcus and above the horizontal limb of the fissure of Sylvius. It is connected, in front, with the ascending parietal convolution beneath the intraparietal sulcus, and with the superior temporal convolution behind, around the posterior extremity of the fissure of Sylvius. The other, the angular, is connected in front with the foregoing and with the middle temporal convolution by a process which curves round the superior temporal or parallel sulcus. It is connected with the occipital lobe by the second annectant gyrus.

The occipital lobe is triangular in shape and forms the posterior extremity of the hemisphere. It rests upon the tentorium. Its external surface is bounded in front by the external parieto-occipital fissure and a line drawn from the extremity of this in the direction of the fissure across the outer surface of the hemisphere. It is continuous below and in front with the temporal lobe, and above and in front with the parietal. It is divided on the outer surface of the hemisphere into three convolutions by two indistinct sulci—the superior and middle occipital sulci. They are directed backward across the lobe, being frequently small and ill-marked; the superior is sometimes continuous with the horizontal portion of the intraparietal sulcus.

The superior occipital convolution is situated above the superior sulcus, and is connected to the superior parietal convolution by the first annectant gyrus.

The middle occipital convolution is situated between the superior and middle occipital sulci, and is connected to the angular convolution by the second annectant gyrus, and to the middle temporal by the third annectant gyrus.

The inferior occipital convolution is situated below the middle occipital sulcus, and is sometimes separated from the external occipito-temporal (fourth temporal) convolution on the under surface of the hemisphere by an inconstant sulcus, the inferior occipital sulcus (posterior extension of third temporal sulcus; see next page). The fourth annectant gyrus unites it with the third temporal gyrus.

The temporal (temporo-sphenoidal) lobe is that portion of the hemisphere which is lodged in the middle fossa of the base of the skull. In front and above it is other of these different parts of the intraparietal sulcus, but that the one in which the three parts of the sulcus are confluent is by far the most constant condition. Sometimes, however, the three parts of the sulcus may be all separate, or the ramus horizontalis confluent with the ramus verticalis inferior, the ramus verticalis superior remaining separate; or, again, the vertical limbs may be confluent and the horizontal limb separate; or, finally, the ramus horizontalis may be joined to the lower end of the ramus verticalis superior, while the lower vertical limb is separate. The connection which sometimes exists between the intraparietal sulcus and the occipital lobe he calls the ramus occipitallis. In the majority of cases, however, the occipital ramus is separated from the main portion of the intraparietal sulcus by a superficial or deep bridging convolution (Journal of Anatomy and Physiology, vol. xxiv. part ii. p. 135).
limited by the fissure of Sylvius; behind, on its external surface, it is connected with the parietal and occipital lobes, and is limited artificially by a line continuing the direction of the external parieto-occipital fissure across the outer surface of the hemisphere. It is divided into three convolutions by two sulci. The superior of these runs parallel to the horizontal limb of the fissure of Sylvius. It is named the superior or first temporal or parallel sulcus, and it is well marked and constant. The second, the middle or second temporal, is not so well marked or constant; it takes the same course at a lower level.

The superior or first temporal convolution is situated between the horizontal limb of the fissure of Sylvius and the superior temporal sulcus. It is continuous behind with the supramarginal convolution.

The middle or second temporal convolution is situated between the superior and middle sulci of the same name, and is continuous behind with the angular and middle occipital convolutions.

The inferior or third temporal convolution is situated below the middle temporal sulcus, and is separated from the external occipito-temporal (fourth temporal) convolution, on the under (mesial) surface of the hemisphere, by a sulcus which is called the inferior or third temporal sulcus. It is connected with the inferior occipital convolution.

The central lobe, or island of Reil (Figs. 467, 468), is situated in the fissure of Sylvius; at the base of the brain it is separated, in front, from the posterior orbital convolution by a nearly transverse sulcus, the anterior sulcus of Reil; externally, from the inferior frontal convolution and the lower ends of the ascending frontal and parietal convolutions by another deep sulcus, the external sulcus of Reil; and posteriorly, from the temporal lobe by a third sulcus, the posterior sulcus of Reil. It is a triangular-shaped (apex downward) prominent cluster of about six convolutions, the gyri operi, so called from being covered in by the gyri bounding the fissure. By the removal of these convolutions the extraventricular part of the corpus striatum would be reached.

These various sulci of Reil, taken together, constitute the sulci limitans insulae. The sulcus centralis insulae divides the lobe into a pre-central and a post-central lobule, of which the former corresponds to, or may be regarded as part of, the frontal lobe; and the latter to the parietal and temporal lobes. Those portions of the corresponding lobes from which the above-mentioned sulci separate the island overlap in the normal condition, and are known as the opercula.

The Mesial Lobes and Fissures of the Hemisphere.—The arrangement of the convolutions in this region is less complex: they are generally well defined, and, some of them being of great length, there is not the same subdivision into smaller lobes as on the external surface (Figs. 469, 470). The fissures on the internal surface are five in number, and are named the calloso-marginal, the parieto-occipital, the calcarine, the collateral, and the dentate.

The calloso-marginal fissure is seen in front, commencing below the anterior extremity of the corpus callosum: it at first runs forward and upward, parallel with the rostrum of the corpus callosum, and, winding round the genu of that body, it continues from before backward, between the upper margin of the hemisphere and the convolution of the corpus callosum, to about midway between the anterior and posterior extremities of the brain, where it turns upward to reach the upper margin of the inner surface of the hemisphere (paracentral fissure of
Wilder) a short distance behind the superior extremity of the furrow of Rolando. It separates the marginal convolution from the gyrus fornicatus or convolution of the corpus callosum (limbic lobe).

The parieto-occipital fissure (internal parieto-occipital) is the continuation of the fissure of the same name seen on the outer surface of the hemisphere. It extends in an oblique direction downward and forward to join the calcarine fissure on a level with the hinder end of the corpus callosum. It separates the quadrate from the cuneate lobe.

The calcarine fissure commences, usually by two branches, at the back of the hemisphere, runs nearly horizontally forward, and is joined by the parieto-occipital fissure, and continues nearly as far as the posterior extremity of the corpus callosum, to terminate a little below the level of this commissure. It separates the cuneate lobe from the fifth temporal or infralcalcarine gyrus, and causes the prominence in the posterior cornu known as the hippocampus minor or calcar avis, whence its name.

The collateral fissure (fourth temporal sulcus) is situated below the preceding, being separated from it by the infralcalcarine gyrus. It runs forward, from the posterior extremity of the brain, nearly as far as the commence ment of the fissure of Sylvius. It runs, at first, between the fourth temporal (below) and infralcalcarine (above) convolutions, and then lies beneath the hippocampal gyrus. It lies below the posterior and middle horn of the lateral ventricle, and causes the prominence in the latter known as the eminentia collateralis.

The dentate or hippocampal fissure commences immediately below the posterior extremity of the corpus callosum, and runs forward to terminate at the recurved part of the hippocampal gyrus. It corresponds with the prominence of the hippocampus major in the descending horn of the lateral ventricle.

The lobes or convolutions seen on the internal surface of the hemisphere are as follows: gyrus fornicatus, marginal, quadrate, cuneate, hippocampal, uncinate, infralcalcarine, fourth temporal, and the paracentral lobule.

The gyrus fornicatus, or convolution of the corpus callosum, is a well-marked
lobe which begins just in front of the anterior perforated space at the base of the brain: it passes forward below the rostrum, and then ascends in front of the genu of the corpus callosum, and runs backward along the upper surface of this body to its posterior extremity, around which it bends to join the hippocampal convolution by a constriction, the *isthmus*. It is bounded below, in front, and above, in the greater part of its extent, by the calloso-marginal fissure, which separates it from the marginal convolution; above and behind its bend it is separated by the *post-limbic fissure* from the quadrate lobe. Between it and the corpus callosum is the *callosal sulcus*.

The **marginal convolution** is situated parallel with the anterior portion of the preceding, and has received its name from its position along the border of the hemisphere. It commences in front of the anterior perforated space, runs along the margin of the longitudinal fissure on the under surface of the orbital lobe, being subdivided by the sulcus for the olfactory tract; it then turns upward to the upper surface of the hemisphere and runs backward, forming the marginal convolution, on the inner surface, to the point where the calloso-marginal fissure turns upward to reach the superior border of the hemisphere. At this point, together with the upper extremities of the ascending frontal and parietal gyri, which are bent over on the inner surface of the hemisphere, it forms the *paracentral lobule*. This convolution is regarded as being on the mesial aspect of the frontal lobe.

The **quadrate lobe** (*precuneus*) is the "marginal" convolution of the longitudinal fissure behind the posterior portion (paracentral fissure) of the calloso-marginal sulcus, lying between this fissure in front and the internal parieto-occipital behind. It is separated by the post-limbic fissure from the gyrus forniciatus below, and is continuous above with the superior parietal convolution.

The **cuneate or occipital lobule** is triangular in shape, being situated between the internal parieto-occipital and calcarine fissures, which, as above mentioned, meet behind the isthmus of the gyrus forniciatus.

The **infracalcarine** (fifth temporal) convolution extends from the posterior extremity of the temporal lobe to join the hippocampal gyrus, being bounded above by the calcarine and its anterior prolongation, after its junction with the parieto-occipital fissure, and separated below from the fourth temporal convolution by the collateral fissure. The back part of this convolution—that is, the part below the

---

*Fig. 470.—Convolutions and fissures of the inner surface of the cerebral hemisphere.*
posterior portion of the calcarine fissure—is sometimes known as the lingual lobule or gyrus.

The fourth temporal convolution is of considerable length, and lies on the inner aspect of the temporal lobe, between the collateral fissure above and the inferior (third) temporal sulcus below, which latter separates it from the inferior (third) temporal convolution on the outer surface of the temporal lobe. Its posterior part is called, at times, the fusiform lobule.

The hippocampal convolution is the downward and forward prolongation, on the mesial surface of the temporal lobe, of the gyrus fornicatus, just after the latter has bent around and beneath the splenium of the corpus callosum. Its direction is toward the apex of the temporal lobe, just before reaching which, however, its anterior extremity is recurved or bent backward in the form of a hook, which is sometimes called the crochet or uncus. It is bounded below by the collateral fissure (anterior portion), and above by the hippocampal or dentate fissure.

The Uncinate Gyrus.—The hippocampal and infracalcarine gyri are, taken together, often described as one gyrus, the uncinate.

Besides the great primary convolutions above named and described, and which can be recognized in almost any well-developed brain, there are a great number of secondary convolutions which pass from one primary convolution to another, and often render the arrangement of the latter somewhat obscure: of these actionable convolutions the connections of the occipital lobe, above mentioned, may be taken as examples.

The Limbic Lobe.—By this term is understood a grouping together of certain portions of the hemisphere which have a peculiar course. That is, beginning anteriorly, they curve forward, upward, and backward, then downward and forward, so that their two extremities lie quite close together. The structures of the limbic lobe have all been described, and are as follows: (1) Gyrus fornicatus and hippocampal gyrus; (2) the supracallosal gyrus (see below); (3) each half of the

---

![Brain diagram](image-url)

**Fig. 471.—Side view of the brain of man, showing the localization of various functions. (After Ferrier.)**

fornix, with its corresponding anterior and posterior pillar and half of the septum lucidum.

The *supracallosal gyrus*, just mentioned, may be regarded as made up of the peduncles of the corpus callosum, the longitudinal strie on the upper surface of the same, and the fascia dentata with its upper part, the fasciola cinerea. These structures are continuous with each other, as has already been mentioned in the description of each. The name *dentate gyrus* is often used to designate the combined fasciola cinerea and fascia dentata.

The boundaries of the limbic lobe are the calloso-marginal fissure, the collateral fissure, and the post-limbic fissure.

**Fig. 472.** Top view of the brain of man, showing the localization of various functions. (After Ferrier.) References the same as in the preceding figure.

**The Olfactory Lobe (Fig. 473).**—This is situated on the orbital lobe (under surface of frontal lobe). In general outline it is long and slender, widest behind. It is divisible into two, anterior and posterior, *olfactory lobules*. The olfactory lobe is developed as a hollow outgrowth from the ventral and lateral part of the corresponding hemisphere vesicle, the cavity of which, in man and primates, is eventually obliterated. In the adult condition the *posterior lobule* is found to have remained on the hemisphere, and thus to form a part of it, while most of the anterior lobule is attached only by a stalk to the posterior, it being freely separable in the rest of its extent; that is, after removal of the membranes.

The *anterior olfactory lobule* is made up of (1) the *olfactory bulb*; (2) the *olfactory tract*; (3) the *trigonum olfactorium*; and (4) the *area of Broca*.

The *olfactory bulb* is an oval mass of a grayish color, which rests on the cribiform plate of the ethmoid bone, and forms the anterior expanded extremity of the slender process of brain-substance, the *olfactory tract* (see page 792). From the under part of this bulb are given off the *olfactory nerves*, which pass through the cribiform foramina and are distributed to the mucous membrane of the nose.
The olfactory tract, when traced backward, divides into two slips or roots, external and internal, at its base. The so-called middle or gray root is the trigonum olfactorium, which is enclosed by the two roots. Traced forward, these two roots unite and form the tract, which is a flat band, narrower in front than behind, and of a somewhat prismoid form on section. It is soft in texture and contains gray matter (neuroglia) in its substance. As it passes forward it is contained in a deep sulcus, the olfactory sulcus, which subdivides the internal orbital convolution, lying on the under surface of the frontal lobe on each side of the longitudinal fissure, and is retained in position by the membrane (pia mater), which covers it. On reaching the cribriform plate of the ethmoid bone it expands into the olfactory bulb.

The trigonum olfactorium and the area of Broca constitute one and the same area of cortical gray matter, bounded internally and posteriorly by a fissure (fissura prima), which separates it from the anterior part of the peduncle of the corpus callosum on its inner aspect, and from the anterior perforated space posteriorly. Externally, this area passes into continuity with the cortical gray matter of the internal orbital gyrus. This area is divided into three districts by the passage across it, from before backward, of the two roots of the olfactory tract. The internal district, lying between the internal root and anterior part of peduncle of corpus callosum (fissura prima intervening) is the area of Broca, continuous with the beginning of the gyrus fornixicus. The middle district, included

![Diagram of the brain](image-url)
between the two roots, is the trigonum olfactorium. The external district, external to the external root, is very small and has no especial name.

The posterior olfactory lobule or anterior perforated space (anterior perforated lamina) is situated at the inner side of the fissure of Sylvius. It is bounded in front by the fissura prima (transverse part) and the orbital convolutions of the frontal lobe; behind, by the optic tract; externally, by the temporal lobe and commencement of the fissure of Sylvius (vallecula); internally, it is continuous with the lamina cinerea. It is crossed internally and posteriorly by the posterior part of the peduncle of the corpus callosum, and externally by the external olfactory root. It is of a grayish color, and corresponds to the under surface of the corpus striatum (lenticular nucleus) and part of the claustrum. It has received its name from being perforated by numerous minute apertures for the transmission of small straight vessels into the substance of the corpus striatum, constituting the antero-median and antero-lateral ganglionic branches of the anterior and middle cerebral arteries.

The Olfactory Roots.—The external root passes outward across the anterior perforated space and the fissure of Sylvius to the temporal lobe—i.e. end of hippocampal gyrus (possibly nucleus amygdalae also)—where it meets the termination of the peduncle of the corpus callosum.

The internal root passes inward and joins the lower end of the gyrus fornictus after bending around and behind the area of Broca, into which also some of its fibres pass.

The trigonum receives a few fibres directly from the end of the tract—i.e. between the divergence of its roots. When these fibres are well marked they constitute the so-called "middle root." From the end of the tract a few fibres also pass directly dorsally into the white matter of the frontal lobe, upper or dorsal root (Henle).

Each root of the olfactory tract is thus seen to be connected with an extremity of the limbic lobe—the external with the end of the hippocampal gyrus, and the internal with the beginning of the gyrus fornictatus.

Under Surface or "Base" of the Encephalon.—The various objects exposed to view on the under surface of the brain, in and near the middle line, are here arranged in the order in which they are met with from before backward (Fig. 473):

In the Middle Line.

Longitudinal fissure.
Under surface of rostrum of corpus callosum and its peduncles.
Lamina cinerea.
Optic commissure.
Optic body.
Infundibulum.
Tuber cinereum.
Corpora albicantia.
Posterior perforated space.
Tuber annulare of pons.
Medulla oblongata (ventral surface).

Each Side of the Middle Line.

Under surface of frontal lobe.
Olfactory bulb.
Olfactory tract.
Olfactory roots.
Anterior perforated space.
Fissure of Sylvius.
Optic tract.
Crusta.
Under surface of temporal lobe.
Under surface of hemisphere of cerebellum.

The longitudinal fissure partially separates the two hemispheres from each other: it divides the two frontal lobes in front, and on raising the cerebellum and pons it will be seen completely separating the two occipital lobes. Of these two portions of the longitudinal fissure, that which separates the occipital lobes is the longer. The intermediate portion of the fissure is filled up by the great transverse band of white matter, the corpus callosum. In the fissure between the two frontal lobes the anterior cerebral arteries ascend on the corpus callosum.

Interpeduncular Space.—Immediately behind the diverging optic tracts, and
between them and the inner margins of the crista or peduncles of the cerebrum (enura cerebri), is a lozenge-shaped interval, the interpeduncular space, in which are found the following parts: the tuber cinereum, infundibulum, pituitary body, corpora albicantia, and the posterior perforated space.

The remaining structures above enumerated have all been previously described, each in its own region.

Structure of the Hemispheres.

Each hemisphere is made up of gray and white matter. The latter constitutes nearly the whole of the deeper portion (medullary centre), and enters into the structure of the convolutions. The gray matter covers in the convolutions, forming the cortex of the hemisphere, and also is collected into three masses or nuclei situated in the hemisphere—the corpus striatum, the claustrum, and the nucleus amygdale. These last might be regarded as subdivisions of one large nucleus, since they are more or less connected in the anterior perforated space.

The white matter of the hemispheres consists of medullated fibres, varying in size and arranged in bundles, separated by neuroglia. They may be divided into three distinct systems, according to the course which they take:

1. Projection fibres, which connect the hemispheres with the medulla oblongata and cord. 2. Transverse or commissural fibres, which connect together the two hemispheres. 3. Association-fibres (Meynert), which connect different structures in the same hemisphere.

1. The projection or peduncular fibres consist of a main body, which originates in the cord and medulla oblongata, forms the longitudinal fibres of the pons, which last are then continued up into the mid-brain, where, as has been before described, the fibres are arranged in two strata, which are separated by the locus niger, the ventral or superficial stratum forming the crista, and the dorsal or deeper stratum the bulk of the tegmentum. The fibres derived from these two sources take a different course, and will have to be separately considered.

The fibres of the crista are derived from the pyramid of the medulla, which fibres are continued upward through the pons to form the crista; they are reinforced in their passage through the crus by accessory fibres derived from the central gray matter around the Sylvian aqueduct, from the nuclei pontis, and from the locus niger (see page 742). Most of the fibres of the crista (except the medial fillet, p. 742) pass into the hemisphere as part of the internal capsule, which last, passing upward, diverges into fibres which radiate forward, upward, and backward, thus constituting the corona radiata. Each fibre of this last-named structure proceeds to the corresponding portion of the cortex, where it becomes the direct prolongation of an axis-cylinder process of a pyramidal cell (see below). Some, if not all, of the fibres of the internal capsule give off collaterals to the optic thalamus and the nucleus caudatus and lenticularis of the corpus striatum.

From these ganglia (see pages 747, 760) there are also fibres which proceed into the internal capsule and the corona radiata, thus forming parts of each in addition to the fibres from the crista. The fibres which arise from the ganglia are more numerous than those which terminate in the ganglia, so that more fibres pass out of the ganglia than pass into them.

The fibres of the tegmentum are continuous with those longitudinal fibres of the pons which are derived from the formation reticularis of the medulla (which see), including also fillet (per corpora quadrigemina) and posterior longitudinal bundle. They are reinforced by fibres from the corpora quadrigemina and corpora geniculata, and from the superior peduncle of the cerebellum. Superiorly, some are lost in the subthalamic region, while others enter the optic thalamus and terminate in its gray matter, whence they are continued into the internal capsule as the various bundles of fibres which have been already referred to both in the description of the optic thalamus and just above. Thus, the tegmental fibres
which help make up the projection fibres do so, not directly, but by the interposition of the optic thalami and corpora striata, between which there are also connecting fibres which run through the internal capsule.

2. The transverse or commissural fibres connect together the two hemispheres. They include (a) the transverse fibres of the corpus callosum, and (b) the anterior commissure.

The corpus callosum, which has already been described, connects together the two hemispheres of the brain, forming their great transverse commissure, penetrating into the medullary substance of the convolutions and intersecting the fibres of the corona radiata. The fibres of the corpus callosum can each be traced either as a direct prolongation of an axis-cylinder process of a pyramidal cell in the gray matter of the cortex, or as a collateral from one of the projection-fibres just described.

The anterior commissure is a round bundle of white fibres which is placed in front of the anterior pillars of the fornix, and appears to connect the corpora striata. It passes outward through the lenticular nucleus of the corpus striatum on each side, and then curves, somewhat twisted on itself, downward and backward into the substance of the temporal lobe, where its fibres radiate from each other.

3. Association-fibres connecting Different Structures in the Same Hemisphere.—These fibres are of two kinds: (1) those which connect adjacent convolutions, and which are termed short association-fibres; (2) those which connect more distant parts in the same hemisphere—the long association-fibres.

The short association-fibres are situated immediately beneath the gray substance of the hemispheres, and connect together adjacent convolutions, arching beneath the cortical matter which lies at the bottom of the fissures.

The long association-fibres include the following:

(a) The uncinate fasciculus connects the convolutions of the frontal and temporal lobe. It passes across the bottom of the Sylvian fissure and traverses the claustrum.

(b) The fillet of the gyrus fornicatus or cingulum is a band of white matter which encircles the hemisphere in an antero-posterior direction, lying in the substance of the convolution of the corpus callosum. Commencing in front at the anterior perforated space, it passes forward and upward parallel with the rostrum, winds round the genu, runs in the convolution from before backward immediately above the corpus callosum, turns round its posterior extremity, and is continued downward and forward in the hippocampal gyrus to its extremity. In its course it is connected with the secondary convolutions of the gyrus fornicatus by short arcuate fibres.

(c) The superior longitudinal fasciculus runs along the convex surface of the hemisphere and connects the frontal lobe with the temporal and occipital.

(d) The inferior longitudinal fasciculus is a collection of fibres which connects the temporal and occipital lobes, running along the outer wall of the middle and posterior cornu.

(e) The perpendicular fasciculus passes vertically through the front part of the occipital lobe, and connects the inferior parietal convolution above with the posterior part (fusiform lobule) of the fourth temporal convolution below.

(f) The fornix connects the corpus albicans with the crochet or uncus of the hippocampal convolution in the manner which has already been described.

The gray matter of the hemisphere is disposed in two regions: 1. The gray matter of the cerebral cortex; 2. The gray matter of the basal ganglia; that is, the corpus striatum and nucleus amygdalae. As the last two have already been described, there remains only the cortex to be considered.

The gray matter of the cortex (Fig. 474) invests the surface of the hemispheres, covering in the convolutions or gyri and lining the intervening fissures or sulci. When a vertical section is made through a gyrus, it is found to be made up of a white centre invested by a portion of the cortex, which last, if examined microscopically, is found to consist of five separate layers, but to this
there are some exceptions. According to Meynert, these exceptions are to be found—(1) in the posterior portion of the occipital lobe; (2) in the gray cortex of the hippocampus major; (3) in the wall of the fissure of Sylvius; and (4) in the olfactory bulb.

The five layers in the common type (from parietal lobe) are as follows: (1) The first (superficial or molecular) layer is principally composed of a matrix of neuroglia, through which a few small ganglion-cells are irregularly distributed, and a nerve-fibre network of both non-medullated and medullated fibres, the latter constituting a delicate white lamina almost in contact with the pia mater. Of the former, the majority come from the processes of the pyramidal cells in the next layer, the remainder being made up of both dendrites (protoplasmic processes) and axis-cylinder processes of the ganglion-cells in this layer.

(2) The second layer consists of numerous small pyramidal cells, which have their long axes vertical to the surface of the convolutions, and are closely aggregated together so as to completely fill the layer. The dendrites of each of these cells extend into the preceding layer, while the axis-cylinder process, starting from the base of the cell, gives off a few collaterals and extends through the white centre of the convolution, and thence to the corpus striatum, as a projection-fibre.

(3) The third layer is made up of cells, which are the same kind as those in the formation of the cornu Ammonis. These cells are large pyramidal cells, arranged vertically to the surface, as was found in the preceding layer, but they are of very much larger size, and increase progressively toward the deeper parts of the layer, and they are much more widely separated from each other, thus forming groups between which are radiating nerve-fibres. This layer is the principal and broadest one of the series, and is at least twice as deep as the preceding layer. The axis-cylinder processes of these cells pass into the white substance, and there become medullated. Previously each gives off a number of collaterals, which also become medullated and form ramifications in the layer.

(4) The fourth layer is termed the layer of polymorphous cells, and consists of numerous, small, irregular cells, each of which has numerous dendrites, but only one axis-cylinder process. This last, from most of the cells, passes into the white centre, but from some it goes peripherally to the first layer and becomes continuous with one of its fibres.

(5) The fifth layer (layer of fusiform cells) consists of a very large proportion of spindle-shaped or fusiform cells, which are the peculiar elements of this layer. They are especially numerous in the inner half, and are arranged horizontally, extending parallel to the surface. The claustrum is made up almost entirely of an accumulation of cells of the same kind.

The white centre lies just beneath the fifth layer, which gradually blends with it. As its fibres radiate into the cortex they become finer, and most of them are continuous, as stated above, with the axis-cylinder processes of the large pyr-
amidal cells in the third layer of the cortex. The collaterals, already referred to, of these processes become medullated and form two plexuses, one along each border of the third layer. These plexuses appear to the naked eye as two fine white lines (Baillarger) in sections of the cortex of a fresh brain.

Special Types of the Gray Matter of the Cortex.—The special types of gray matter of the cortex are the following:

1. On the posterior portion of the occipital lobe, near the calcarine fissure, the gray matter consists of six or eight layers. This is produced by the intercalation of intermediate small, irregular cells, similar to those forming the fourth layer of the typical cortex. Furthermore, the large pyramidal cells of the typical third layer are very few, while, on the other hand, in the upper part of the ascending frontal convolution (psycho-motor region) these pyramidal cells of the third layer are, many of them, of unusual size.

2. In the gray matter of the cortex of the hippocampus major or cornu Ammonis pyramidal cells are found, such as have been described in the third layer of the typical cortex. They constitute the greater part of the structure, the fourth and fifth layers being absent. Hence this layer is called the formation of the cornu Ammonis. The bases of these cells are close under the white lamina (alveus) which covers the hippocampus on its ventricular aspect. The second layer—i.e., toward the hippocampal fissure—contains no cells. It is represented by a closely interwoven arborization of the dendrites (protoplasmic processes) of the pyramidal cells just mentioned, of which the axis-cylinder processes pass, in the opposite direction, into the alveus. Finally, beyond the second layer is the first layer of the gray matter of the hippocampus, or, as it is termed, the granular formation (Meynert), and consists of numerous small, irregular cells, which resemble the nerves-corporcles found in the internal granule-layer of the retina.

3. In the Sylvian fissure the fifth layer of the cortex contains an unusual number of fusiform cells; hence this layer, in this region, is called the "cualstral formation," because of the number of the same kind of cells in the structure of the culastrum.

4. In the olfactory bulb, which is a portion of the cerebral hemispheres, forming "a cap superimposed upon a conical process of the cerebrum," is another variety of structure, differing from the type of the cortex of the hemispheres. The bulb consists of both gray and white matter, and in most of the lower animals retains a central cavity lined by epithelium, around which is a layer of neuroglia, surrounded in its turn by white fibres, the whole being enclosed by gray matter. In man the central cavity is obliterated, and in the "centre" of the bulb is found neuroglia surrounded in section by a flattened ring (medullary ring) of white fibres. The gray matter is now exceedingly thin dorsally, but very thick ventrally, and in section this central portion shows the following layers from below upward: 1. The olfactory nerve-layer, consisting of a plexus of non-medullated nerve-fibres derived from the nerves which supply the olfactory region. These fibres pass downward through the foramina in the cribriform plate of the ethmoid, and dorsally into the glomeruli of 2, the stratum glomerulosum, consisting of nodulated masses (the glomeruli), each mass consisting of a dense interlacement of fibres, which are partly the prolongations of the olfactory fibres just mentioned, and partly the dendrites of the mitral cells in the superjacent part of the next layer. Small neuroglia-cells also are found in these glomeruli. 3. The granular layer, consisting of (a) small irregular nerve-cells resembling those of the granule-layer of the cortex of the cerebellum; (b) a deeper layer (next to the stratum glomerulosum) of large, conical cells (mitral cells). The dendrites of these pass down to the glomeruli (see above), while their axis-cylinder processes (medullated) pass upward between small cells of the granule-layer to the medullary ring, with the fibres of which, after bending sharply backward, they become continuous, and thence pass backward along the olfactory tract toward the base of the brain; that is, the fibres of the medullary ring are the continuations of these processes.
Weight of the Encephalon.—The average weight of the brain in the adult male is 49\(\frac{1}{2}\) oz., or a little more than 3 lbs. avoirdupois; that of the female 44 oz.; the average difference between the two being from 5 to 6 oz. The prevailing weight of the brain in the male ranges between 46 oz. and 53 oz., and in the female between 41 oz. and 47 oz. In the male the maximum weight out of 278 cases was 65 oz., and the minimum weight 34 oz. The maximum weight of the adult female brain, out of 191 cases, was 56 oz., and the minimum weight 31 oz. According to Luschka, the average weight of a man’s brain is 1424 grammes (about 45 oz.), of a woman’s 1272 grammes (about 41 oz.), and, according to Krause, 1570 grammes (about 48\(\frac{1}{2}\) oz.) for the male, and 1350 (about 43 oz.) for the female. It appears that the weight of the brain increases rapidly up to the seventh year, more slowly to between sixteen and twenty, and still more slowly to between thirty and forty, when it reaches its maximum. Beyond this period, as age advances and the mental faculties decline, the brain diminishes slowly in weight, about an ounce for each subsequent decennial period. These results apply alike to both sexes.

The size of the brain was formerly said to bear a general relation to the intellectual capacity of the individual. Cuvier’s brain weighed rather more than 64 oz., that of the late Dr. Abercrombie 63 oz., and that of Dupuytren 62\(\frac{3}{4}\) oz. On the other hand, the brain of an idiot seldom weighs more than 23 oz. But these facts are by no means conclusive, and it is well known that these weights have been equalled by the brains of persons who never displayed any remarkable intellect. Dr. Haldenman of Cincinnati has recorded the case of a mulatto, aged forty-five, whose brain weighed 68\(\frac{1}{2}\) oz.; he had been a slave, and was never regarded as particularly intelligent; he was illiterate, but is said to have been reserved, meditative, and economical. Dr. Ensor, district medical officer at Port Elizabeth, reports that the brain of Carey, the Irish informer, weighed 61 oz. M. Nikiforoff has published an article on the subject of the weight of brains in the Novosti. According to him, the weight of the brain has no influence whatever on the mental faculties. It ought to be remembered that the significance of the weight of the brain should depend upon the proportion it bears to the dimensions of the whole body and to the age of the individual. It is equally important to know what was the cause of death, for long illness or old age exhausts the brain. To define the real degree of development of the brain it is therefore necessary to have a knowledge of the condition of the whole body, and, as this is usually lacking, the mere record of weight possesses little significance.

The human brain is heavier than that of all the lower animals, excepting the elephant and whale. The brain of the former weighs from eight to ten pounds; and that of a whale, in a specimen seventy-five feet long, weighed rather more than five pounds.

Cerebral Localization and Topography.—Within the last few years physiological and pathological research have gone far to prove that the surface of the brain may be mapped out into series of definite areas, each one of which is intimately connected with some well-defined function. And this is especially true with regard to the convolutions on either side of the fissure of Rolando, which are believed by most physiologists of the present day to be concerned in motion, those grouped around the fissure being associated with movements of the extremities of the opposite side of the body, and those around the lower end of the fissure being related to movements of the mouth and tongue.

This is not the place, nor can space be given, to describe these localities. But the two accompanying woodcuts from Ferrier (Figs. 471, 472) have been introduced, and will serve to indicate the position of these areas as far as they have been at present ascertained.

The relation of the principal fissures and convolutions of the cerebrum to the outer surface of the scalp has been the subject of much recent investigation, and many systems have been devised by which one may localize these parts from an examination of the external surface of the head.

These plans can only be regarded as approximately correct for several reasons: in the first place, because the relations of the convolutions and sulci to the surface are found to be very variable in different individuals; secondly, because the surface area of the scalp is greater than the surface area of the brain, so that lines drawn on the one cannot correspond exactly to sulci or convolutions on the other; and thirdly, because the sulci and convolutions in two individuals are never precisely alike. Nevertheless, the principal fissures and convolutions can be mapped
out with sufficient accuracy for all practical purposes, so that any particular convolution can be generally exposed by removing with the trephine a certain portion of the skull's area.

The various landmarks on the outside of the skull, which can be easily felt, and which serve as indications of the position of the parts beneath, have been already referred to (see page 222), and the relation of the fissures and convolutions to these landmarks is as follows:

**Longitudinal Fissure.**—This corresponds to a line drawn from the glabella at the root of the nose to the external occipital protuberance.

**The Fissure of Sylvius.**—The position of the fissure of Sylvius and its horizontal limb is marked by a line starting from a point one inch and a quarter horizontally behind the external angular process of the frontal bone to a point three-quarters of an inch below the most prominent point of the parietal eminence. The first three-quarters of an inch will represent the main fissure, the remainder the horizontal limb. The bifurcation of the fissure is, therefore, two inches behind and about a quarter of an inch above the level of the external angular process. The ascending limb of the fissure passes upward from this point parallel to, and immediately behind, the coronal suture.

**Fissure of Rolando.**—To find the upper end of the fissure of Rolando, a measurement should be taken from the glabella to the external occipital protuberance. The position of the top of the sulcus will be, measuring from in front, 55.6 per cent. of the whole distance from the glabella to the external occipital protuberance. Professor Thane adopts a somewhat simpler method. He divides the distance from the glabella to the external occipital protuberance over the top of the head into two equal parts, and, having thus defined the middle point of the vertex, he takes half an inch behind it as the top of the sulcus. This is not quite so accurate as the former method, but it is sufficiently so for all practical purposes, and on account of its simplicity is very generally adopted. From this point the fissure runs downward and forward for $3\frac{3}{4}$ inches, its axis making an angle of 67° with the middle line. In order to mark this groove, two strips of metal may be employed—one, the shorter, being fixed to the middle of the other at the angle mentioned. If the longer strip is now placed along the sagittal suture so that the junction of the two strips is over the point corresponding to the top of the furrow, the shorter, oblique strip will indicate the direction and $3\frac{3}{4}$ inches will mark the length of the furrow. Dr. Wilson has devised an instrument, called a cyrtometer, which combines the scale of measurements for

---

**Fig. 473.—Drawing to illustrate cranio-cerebral topography.** (Macalister.) Taken from a cast prepared by Professor Cunningham.
localizing the fissure with data for representing its length and direction. Professor Thane gives the lower end of the furrow as "close to the posterior limb, and about half an inch behind the bifurcation of the fissure of Sylvius." So that, according to this anatomist, a line drawn from a point half an inch behind the mid-point between the glabella and external occipital protuberance to this spot would mark out the fissure of Rolando. Dr. Reid adopts a different method (Fig. 476). He first indicates, on the surface the longitudinal fissure and the horizontal limb of the fissure of Sylvius (as above). He then draws two perpendicular lines from his "base-line" (that is, a line from the lowest part of the infra-orbital margin through the middle of the external auditory meatus to the back of the head) to the top of the cranium, one (D E, Fig. 476) from the depression in front of the external auditory meatus, and the other (F G, Fig. 476) from the posterior border of the mastoid process at its root. He has thus described on the surface the head a four-sided figure (F D G E, Fig. 476), and a diagonal line from the posterior superior angle to the anterior perpendicular line where it is crossed by the fissure of Sylvius will represent the furrow.

The parieto-occipital fissure on the upper surface of the cerebrum runs outward at right angles to the great longitudinal fissure for about an inch, from a point one-fifth of an inch in front of the lambda (posterior fontanelle). Reid states that if the horizontal limb of the fissure of Sylvius be continued outward to the sagittal suture, the last inch of this line will indicate the position of the sulcus.

The precentral sulcus lies in a line drawn vertically downward from the point of junction of the sagittal and coronal sutures. It begins four-fifths of an inch in front of the middle of the fissure of Rolando, and extends nearly, but not quite, to the horizontal limb of the fissure of Sylvius.

The superior frontal fissure runs backward from the supra-orbital notch, parallel with the line of the longitudinal fissure to two-fifths of an inch in front of the line indicating the position of the fissure of Rolando.

The inferior frontal fissure follows the course of the superior temporal ridge on the frontal bone.

The intraparietal fissure begins on a level with the junction of the middle and lower third of the fissure of Rolando, on a line carried across the head from the back of the root of one auricle to that of the other. After passing upward it curves backward, lying parallel to the longitudinal fissure, midway between it and the parietal eminence; it then curves downward to end midway between the posterior fontanelle and the parietal eminence.

1 Lancet, vol. i., 1888, p. 408.
THE CRANIAL NERVES.

The cranial nerves arise from some part of the cerebro-spinal centre, and are transmitted through foramina in the base of the cranium. They have been named numerically, according to the order in which they pass through the dura mater lining the base of the skull. Other names are also given to them, derived from the parts to which they are distributed or from their functions. Taken in their order, from before backward, they are as follows:

1st. Olfactory. 7th. Facial (Portio dura).
2d. Optic. 8th. Auditory (Portio mollis).
4th. Pathetic. 10th. Pneumogastric (Par vagum).

All the cranial nerves are connected to some part of the surface of the brain. This is termed their superficial or apparent origin. But their fibres may, in all cases, be traced deeply into the substance of the brain to some special centre of gray matter, termed a nucleus. This is called their deep or real origin. The nerves, after emerging from the brain at their apparent origin, pass through foramina or tubular prolongations in the dura mater, leave the skull through foramina in its base, and pass to their final distribution.

First Nerve (Fig. 473, page 783).

The First Cranial or Olfactory Nerves, the special nerves of the sense of smell, are about twenty in number. They are given off from the under surface of the olfactory bulb, an oval mass of a grayish color, which rests on the cribriform plate of the ethmoid bone, and forms the anterior expanded extremity of a slender process of brain-substance, named the olfactory tract (see page 783). The olfactory tract, when traced backward, divides into three slips or roots at its base. The middle root is attached to the under surface of the frontal lobe, just in front of the anterior perforated space. The external root passes outward, round the anterior perforated space, across the fissure of Sylvius to the temporo-sphenoidal lobe. The internal root passes inward, and joins the lower end of the gyrus fornicatus.

These three roots unite and form a flat band, narrower in the middle than at either extremity, and of a somewhat prismoid form on section. It is soft in texture and contains a considerable amount of gray matter in its substance. As it passes forward it is contained in a deep sulcus, the olfactory sulcus, between two convolutions, lying on the under surface of the frontal lobe, on either side of the longitudinal fissure, and is retained in position by the arachnoid membrane, which covers it. On reaching the cribriform plate of the ethmoid bone it expands into the olfactory bulb. From the under part of this bulb are given off the olfactory nerves, which pass through the cribiform foramina and are distributed to the mucous membrane of the nose. Each nerve is surrounded by a tubular prolongation from the dura mater and pia mater; the former being lost on the periosteum lining the nose; the latter, in the neurilemma of the nerve. The nerves, as they enter the nares, are divisible into three groups: an inner group, larger than those on the outer wall, spread out over the upper third of the septum; a middle set, confined to the roof of the nose; and an outer set, which are distributed over the superior and middle turbinated bones and the surface of the ethmoid in front of them. As the filaments descend they unite in a plexiform network, and are believed by most observers to terminate in the cells of Schwann. The olfactory differ in structure from other nerves in being composed exclusively of non-medullated fibres. They are deficient in the white substance of Schwann, and consist of axis-cylinders, with a distinct nucleated sheath, in which there are, however, fewer nuclei than in ordinary non-medullated fibres.
Surgical Anatomy.—In severe injuries to the head the olfactory bulb may become separated from the olfactory nerves, thus producing loss of the sense of smelling (anosmia), and with this a considerable loss in the sense of taste, as much of the perfection of the sense of taste is due to the rapid substances being also odorous and simultaneously exciting the sense of smell.

Second Nerve (Fig. 477).

The Second or Optic Nerve, the special nerve of the sense of sight, is distributed exclusively to the eyeball. The nerves of opposite sides are connected together at the commissure, and from the back of the commissure they may be traced to the brain, under the name of the optic tracts.

The optic tract, at its connection with the brain, is divided into two bands, external and internal. The external arises from the external geniculate body and from the under part of the pulvinar of the optic thalamus, and receives most of the fibres of the brachium of the superior corpus quadrigeminnum. The internal arises from beneath the internal geniculate body, from which it derives fibres, and joins with the other band to form the optic tract. From this origin the tract winds obliquely across the surface of the crista in the form of a flattened band, destitute of neurilemma and attached to the crista by its antero-superior margin. It then assumes a cylindrical form, and, as it passes forward, is connected with the tuber cinereum and lamina cinerea. It finally joins with the tract of the opposite side to form the optic commissure.

The commissure or chiasma, somewhat quadrilateral in form, rests upon the optic groove of the sphenoid bone, being bounded, above, by the lamina cinerea; behind, by the tuber cinereum; on either side, by the anterior perforated space. Within the commissure the optic nerves of the two sides undergo a partial decussation. The fibres which form the inner margin (inferior commissure of Gudden) of each tract are continued across from one to the other side of the brain. These may be regarded as commissural fibres (intercerebral) between the internal geniculate bodies. Some fibres are continued across the anterior border of the chiasma, and connect the optic nerves of the two sides, having no relation with the optic tracts. They may be regarded as commissural fibres between the two retinae (inter-retinal fibres). The outer fibres of each tract are continued into the optic nerve of the same side. The central fibres of each tract are continued into the optic nerve of the opposite side, decussating in the commissure with similar fibres of the opposite tract.

The optic nerves arise from the fore part of the commissure, and, diverging from one another, become rounded in form and firm in texture, and are enclosed in a sheath derived from the arachnoid. As each nerve passes through the corresponding optic foramen it receives a sheath from the dura mater; and as it enters the orbit this sheath subdivides into two layers, one of which becomes continuous with the peristium of the orbit; the other forms the proper sheath of the nerve and

1 The presence of these fibres has been doubted by some observers, but they have been recently asserted to exist by Stilling.

2 A specimen of congenital absence of the optic commissure is to be found in the Museum of the Westminster Hospital. (See also Henle, Nervenlehre, p. 393, ed. 2.)
surgical Anatomy.—The optic nerve is peculiarly liable to become the seat of neuritis or undergo atrophy in affections of the central nervous system, and, as a rule, the pathological relationship between the two affections is exceedingly difficult to trace. There are, however, certain points in connection with the anatomy of this nerve which tend to throw light upon the frequent association of these affections with intracranial disease: (1) From its mode of development (see page 123) and from its structure the optic nerve must be regarded as a prolongation of the brain-substance, rather than as an ordinary cerebro-spinal nerve. (2) As it passes from the brain it receives sheaths from the three cerebral membranes—a perineural sheath from the pia mater, an intermediate sheath from the arachnoid, and an outer sheath from the dura mater, which is also connected with the periosteum as it passes through the optic foramen. These sheaths are separated from each other by spaces which communicate with the subdural and subarachnoid spaces respectively. The innermost or perineural sheath sends a process around the arteria centralis retinae into the interior of the nerve, and enters intimately into the structure of the nerve. Thus inflammatory affections of the meninges or of the brain may readily extend themselves along these spaces or along the interstitial connective tissue in the nerve.

The course of the fibres in the optic commissure has an important pathological bearing, and has been the subject of much controversy. Microscopic examination, experiments, and pathology all seem to point to the fact that there is a partial decussation of the fibres, each tract supplying the corresponding half of each eye, so that the right tract supplies the right half of each eye, and the left tract the left half of each eye. At the same time, Charcot believes—and his view has met with general acceptance—that the fibres which do not decussate at the optic commissure have already decussated in the corpora quadrigemina, so that lesion of the cerebral centre of one side causes complete blindness of the opposite eye, because both sets of decussating fibres are destroyed. Whereas should one tract—say the right—be destroyed by disease, there will be blindness of the right half of both retinae.

An antero-posterior section through the commissure would divide the decussating fibres, and would therefore produce blindness of the inner half of each eye: while a section at the margin of the side of the optic commissure would produce blindness of the external half of the retina of the same side.

The optic nerve may also be affected in injuries or diseases involving the orbit, in fractures of the anterior fossa of the base of the skull, in tumors of the orbit itself, or those invading this cavity from neighboring parts.

Third Nerve (Figs. 384, 479, 480, 481, 486).

The Third or Motor Oculi Nerve supplies all the muscles of the orbit, except the Superior oblique and External rectus; it also sends motor filaments to the iris and the ciliary muscle. It is a rather large nerve, of rounded form and firm texture. Its apparent origin is from the inner surface of the crus cerebri, immediately in front of the pons Varolii.

The deep origin may be traced through the locus niger and tegmentum of the crus to a nucleus situated on either side of the median line beneath the floor of the aqueduct of Sylvius. On emerging from the brain the nerve is invested with a sheath of pia mater, and enclosed in a prolongation from the arachnoid. It then pierces the dura mater in front of and external to the posterior clinoid process, passing between the two processes from the free and attached borders of the tentorium, which are prolonged forward to be connected with the anterior and posterior clinoid processes of the sphenoid bone. It passes along the outer wall of the cavernous sinus, above the other orbital nerves, receiving in its course one or two filaments from the cavernous plexus of the sympathetic and from the ophthalmic division of the fifth nerve. It then divides into two branches, which enter the orbit through the sphenoidal fissure between the two heads of the External rectus muscle. On passing through the fissure the nerve is placed below the fourth and the frontal and lachrymal branches of the ophthalmic nerve, and has passing between its two divisions the nasal nerve.
The superior division, the smaller, passes inward over the optic nerve, and supplies the Superior rectus and Levator palpebrae. It occasionally communicates with the ganglionic branch of the nasal nerve.

The inferior division, the larger, divides into three branches. One passes beneath the optic nerve to the Internal rectus; another, to the Inferior rectus; and the third, the largest of the three, passes forward between the Inferior and External recti to the Inferior oblique. From this latter a short, thick branch is given off to the lower part of the lenticular ganglion, which forms its inferior root. It also gives off one or two filaments to the Inferior rectus. All these branches enter the muscles on their ocular surface, except that to the Inferior oblique, which enters its posterior border.

Surgical Anatomy.—Paralysis of the third nerve may be the result of many causes: as cerebral disease; conditions causing pressure on the cavernous sinus; periostitis of the bones entering into the formation of the sphenoidal fissure. It results, when complete, in (1) ptosis, or drooping of the upper eyelid, in consequence of the Levator palpebrae being paralyzed; (2) external strabismus, on account of the unopposed action of the External rectus muscle, which is not supplied by the third nerve, and is not therefore paralyzed; (3) dilatation of the pupil, because the sphincter fibres of the iris are paralyzed; (4) loss of power of accommodation, as the sphincter pupillae, the ciliary muscle, and the Internal rectus are paralyzed; (5) slight prominence of the eyeball, from the compressing action of the Superior oblique, which is not paralyzed. Occasionally paralysis may affect only a part of the nerve; that is to say, there may be, for example, a dilated and fixed pupil, with ptosis, but no other signs. Irritation of the nerve causes spasm of one or other of the muscles supplied by it; thus, there may be internal strabismus from spasm of the Internal rectus; accommodation for near objects only from spasm of the ciliary muscle, or myosis, contraction of the pupil, from irritation of the sphincter of the pupil.
Fourth Nerve (Figs. 384, 479, 486).

The Fourth or Trochlear Nerve (pathetic), the smallest of the cranial nerves, supplies the Superior oblique muscle. Its apparent origin is behind the corpora quadrigemina, from the valve of Vieussens, in the upper surface of which the two nerves decussate. Its deep origin may be traced to the nucleus in the floor of the aqueduct of Sylvius immediately below that of the third nerve, with which it is continuous. After emergence from the surface of the valve of Vieussens, the nerve winds across the superior peduncle of the cerebellum and round the crus ta of the mid-brain, immediately above the pons Varoli, pierces the dura mater in the free border of the tentorium cerebelli just behind, and external to, the posterior clinoid process, and passes forward in the outer wall of the cavernous sinus, between the third nerve and the ophthalmic division of the fifth. It then crosses the third nerve, and enters the orbit through the sphenoidal fissure. It now lies at the inner extremity of the fissure internal to the frontal nerve. In the orbit it passes inward above the origin of the Levator palpebrae, and finally enters the orbital surface of the Superior oblique muscle.

In the outer wall of the cavernous sinus this nerve receives some filaments from the ophthalmic division of the fifth as well as from the cavernous plexus of the sympathetic, and gives off a recurrent branch, which passes backward between the layers of the tentorium, dividing into two or three filaments which may be traced as far back as the wall of the lateral sinus. In the sphenoidal fissure it occasionally gives off a branch to assist in the formation of the lachrymal nerve.

Surgical Anatomy.—The fourth nerve when paralyzed causes loss of function in the Superior oblique, so that the patient is unable to turn his eye downward and outward. Should the patient attempt to do this, the eye on the affected side is twisted inward, producing diplopia or double vision. Accordingly, it is said that the first symptom of this disease which presents itself is giddiness when going down hill or in descending stairs, owing to the double vision induced by the patient looking at his steps while descending.

Fifth Nerve.

The Fifth or Trigeminal Nerve (trigeminus) is the largest cranial nerve. It resembles a spinal nerve (1) in arising by two roots; (2) in having a ganglion developed on its posterior root; and (3) in its function, since it is a compound nerve. It is the great sensory nerve of the head and face and the motor nerve of the muscles of mastication. Its upper two divisions are entirely sensory; the
third division is partly sensory and partly motor. It arises by two roots: of these the anterior is the smaller, and is the motor root; the posterior, the larger and sensory. Its superficial origin is from the side of the pons Varolii, nearer to the upper than the lower border. The smaller root consists of three or four bundles; the larger root consists of numerous bundles of fibres, varying in number from seventy to a hundred. The two roots are separated from one another by a few of the transverse fibres of the pons. The deep origin of the larger or sensory root is from a nucleus in the pons, just below the floor and just internal to the margin of the upper half of the fourth ventricle. The deep origin of the smaller or motor root is from a nucleus internal to the sensory root, and just external to the fascicular teres on the upper half of the floor of the fourth ventricle. The two roots of the nerve pass forward through an oval opening (canum Meckelii) in the dura mater, on the superior border of the petrous portion of the temporal bone, above the internal auditory meatus: they then run between the bone and the dura mater to the apex of the petrous portion of the temporal bone, where the fibres of the sensory root form a large, semilunar ganglion (Gasserian), while the motor root passes beneath the ganglion without having any connection with it, and joins outside the cranium with one of the trunks derived from it.

The Gasserian or semilunar ganglion is lodged in a depression near the apex of the petrous portion of the temporal bone. It is of somewhat crescentic form, with its convexity turned forward. Its upper surface is intimately adherent to the dura mater. Besides the small or motor root, the large superficial petrosal nerve lies underneath the ganglion.

Branches of Communication.—This ganglion receives, on its inner side, filaments from the carotid plexus of the sympathetic. Branches of Distribution.—It gives off minute branches to the tentorium cerebelli and the dura mater in the middle fossa of the cranium. From its anterior border, which is directed forward and outward, three large branches proceed—the ophthalmic, superior maxillary, and inferior maxillary. The ophthalmic and superior maxillary consist exclusively of fibres derived from the larger root and ganglion, and are solely nerves of common sensation. The third division, or inferior maxillary, is joined outside the cranium by the motor root. This, therefore, strictly speaking, is the only portion of the fifth nerve which can be said to resemble a spinal nerve.

Ophthalmic Nerve (Figs. 384, 479, 481, 482, 486).

The Ophthalmic, or first division of the fifth, is a sensory nerve. It supplies the eyeball, the lachrymal gland, the mucous lining of the eye and nasal fossae, and the integument of the eyebrow, forehead, and nose. It is the smallest of the three divisions of the fifth, arising from the upper part of the Gasserian ganglion. It is a short, flattened band, about an inch in length, which passes forward along the outer wall of the cavernous sinus, below the other nerves, and just before entering the orbit, through the sphenoidal fissure, divides into three branches—lachrymal, frontal, and nasal.

Branches of Communication.—The ophthalmic nerve is joined by filaments from the cavernous plexus of the sympathetic, communicates with the third and sixth nerves, and is not unfrequently joined with the fourth.

Branches of Distribution.—It gives off recurrent filaments (nervi tentorii) which pass between the layers of the tentorium along with a branch from the fourth nerve, and then divides into

1 A Viennese anatomist, Raimund Balthasar Hirsch (1765), was the first who recognized the ganglionic nature of the swelling on the sensory root of the fifth nerve, and called it, in honor of his otherwise unknown teacher, Jon. Laur. Gasser, the "Ganglion Gasserii." Julius Casserius, whose name is given to the musculo-cutaneous nerve of the arm, was professor at Padua, 1545-1605. (See Hyrtl, Lehrbuch der Anatomie, p. 895 and p. 55.)
The Lachrymal is the smallest of the three branches of the ophthalmic. Not unfrequently it arises by two filaments, one from the ophthalmic, the other from the fourth. It passes forward in a separate tube of dura mater and enters the orbit through the narrowest part of the sphenoidal fissure. In the orbit it runs along the upper border of the External rectus muscle with the lachrymal artery, and sends off a recurrent branch which joins the orbital branch of the superior maxillary nerve, and occasionally takes the place of the temporal branch of this nerve, which is then absent. Within the lachrymal gland it gives off several filaments, which supply the gland and the conjunctiva. Finally, it pierces the tarsal ligaments, and terminates in the integument of the upper eyelid, joining with filaments of the facial nerve.

The Frontal is the largest division of the ophthalmic, and may be regarded, both from its size and direction, as the continuation of the nerve. It enters the orbit above the muscles through the highest and broadest part of the sphenoidal fissure, and runs forward along the middle line, between the Levator palpebrae and the periosteum. Midway between the apex and base of the orbit it divides into two branches, supratrochlear and supra-orbital.

The supratrochlear branch, the smaller of the two, passes inward above the pulley of the Superior oblique muscle, and gives off a descending filament, which joins with the infratrochlear branch of the nasal nerve. It then escapes from the orbit between the pulley of the Superior oblique and the supra-orbital foramen, curves up on to the forehead close to the bone, and ascends beneath the Corrugator supercilii and Occipito-frontalis muscles, and supplies the integument of the lower part of the forehead on either side of the middle line.

The supra-orbital branch passes forward through the supra-orbital foramen, and gives off, in this situation, palpebral filaments to the upper eyelid. It then ascends upon the forehead, and terminates in cutaneous and pericranial branches. The cutaneous branches, two in number, an inner and an outer, supply the integument of the cranium as far back as the occiput. They are at first situated beneath the Occipito-frontalis, the inner branch perforating the frontal portion of the muscle, the outer branch its tendinous aponeurosis. The pericranial branches are distributed to the pericranium over the frontal and parietal bones.

The Nasal nerve is intermediate in size between the frontal and lachrymal, and more deeply placed than the other branches of the ophthalmic. It enters the orbit

![Fig. 481.—Nerves of the orbit and ophthalmic ganglion. Side view.](Image)
between the two heads of the External rectus, and between the two divisions of the third nerve, and passes obliquely inward across the optic nerve, beneath the Superior oblique and Superior rectus muscles, to the inner wall of the orbit, where it enters the anterior ethmoidal foramen. It then enters the cavity of the cranium, traverses a shallow groove on the cribriform plate of the ethmoid bone, and passes down, through the slit by the side of the crista galli, into the nose, where it gives off two branches, an internal and an external. The **internal branch** supplies the mucous membrane near the fore part of the septum of the nose. The **external branch** supplies a few filaments to the mucous membrane covering the fore part of the outer wall of the nares as far as the inferior spongy bone. The nerve then descends in a groove on the back of the nasal bone and leaves the cavity of the nose, between the lower border of the nasal bone and the upper lateral cartilage of the nose, and, passing down beneath the Compressor nasi, supplies the integument of the ala and the tip of the nose, joining with the facial nerve.

The branches of the nasal nerve are the **ganglionic, ciliary, and infratrochlear**.

The **ganglionic** is a slender branch, about half an inch in length, which usually arises from the nasal, between the two heads of the External rectus. It passes forward on the outer side of the optic nerve, and enters the superior and posterior angle of the ciliary ganglion, forming its superior or long root. It is sometimes joined by a filament from the cavernous plexus of the sympathetic or from the superior division of the third nerve.

The **long ciliary nerves**, two or three in number, are given off from the nasal as it crosses the optic nerve. They join the short ciliary nerves from the ciliary ganglion, pierce the posterior part of the sclerotic, and, running forward between it and the choroid, are distributed to the ciliary muscles, iris, and cornea.

The **infratrochlear branch** is given off just before the nasal nerve passes through the anterior ethmoidal foramen. It runs forward along the upper border of the Internal rectus, and is joined, beneath the pulley of the Superior oblique, by a filament from the supratrochlear nerve. It then passes to the inner angle of the eye, and supplies the integument of the eyelids and side of the nose, the conjunctiva, lacrimal sac, and caruncula lachrymalis.

**Ophthalmic Ganglion** (Figs. 481, 482).

Connected with the three divisions of the fifth nerve are four small ganglia. With the first division is connected the **ophthalmic ganglion**; with the second division, the **sphenopalatine** or **Meckel's ganglion**; and with the third, the **otic** and **submaxillary ganglia**. All the four receive sensory filaments from the fifth, and motor and sympathetic filaments from various sources; these filaments are called the **roots of the ganglia**.

The **Ophthalmic, Lenticular, or Ciliary Ganglion** is a small, quadrangular, flattened ganglion, of a reddish-gray color, and about the size of a pin's head, situated at the back part of the orbit between the optic nerve and the External rectus muscle, lying generally on the outer side of the ophthalmic artery. It is enclosed in a quantity of loose fat, which makes its dissection somewhat difficult.

Its **branches of communication**, or **roots**, are three, all of which enter its posterior border. One, the long or sensory root, is derived from the nasal branch of the ophthalmic and joins its superior angle. The second, the short or motor root, is a short, thick nerve, occasionally divided into two parts, which is derived from the branch of the third nerve to the Inferior oblique muscle, and is connected with the inferior angle of the ganglion. The third, the sympathetic root, is a slender filament from the cavernous plexus of the sympathetic. This is frequently blended with the long root, though it sometimes passes to the ganglion separately. According to Tiedemann, this ganglion receives a filament of communication from the sphenopalatine ganglion.
Its branches of distribution are the short ciliary nerves. These are delicate filaments, from six to ten in number, which arise from the fore part of the ganglion.
in two bundles, connected with its superior and inferior angles; the lower bundle is the larger. They run forward with the ciliary arteries in a wavy course, one set above and the other below the optic nerve, and are joined by the long ciliary nerves from the nasal. They pierce the sclerotic at the back part of the globe, pass forward in delicate grooves on its inner surface, and are distributed to the ciliary muscle, iris, and cornea. Tiedemann has described one small branch as penetrating the optic nerve with the arteria centralis retinae.

**Superior Maxillary Nerve (Fig. 483).**

The **Superior Maxillary**, or second division of the fifth, is a sensory nerve. It is intermediate, both in position and size, between the ophthalmic and inferior maxillary. It commences at the middle of the Gasserian ganglion as a flattened plexiform band, and passes forward through the foramen rotundum, where it becomes more cylindrical in form and firmer in texture. It then crosses the sphen-maxillary fossa, enters the orbit through the sphen-maxillary fissure, traverses the infra-orbital canal in the floor of the orbit, and appears upon the face at the infra-orbital foramen. At its termination the nerve lies beneath the Levator labii superioris muscle, and divides into a leash of branches, which spread out upon the side of the nose, the lower eyelid, and upper lip, joining with filaments of the facial nerve.

**Branches of Distribution.**—The branches of this nerve may be divided into four groups: 1. Those given off in the cranium. 2. Those given off in the sphen-maxillary fossa. 3. Those in the infra-orbital canal. 4. Those on the face.

The **meningeal branch** is given off directly after its origin from the Gasserian ganglion, and supplies the dura mater, communicating with a meningeal branch from the inferior maxillary nerve.

The **orbital** or **temporo-malar branch** arises in the sphen-maxillary fossa, enters the orbit by the sphen-maxillary fissure, and divides at the back of that cavity into two branches, temporal and malar.

The **temporal branch** runs in a groove along the outer wall of the orbit (in the malar bone), receives a branch of communication from the lachrymal, and, passing through a foramen in the malar bone, enters the temporal fossa. It ascends between the bone and substance of the Temporal muscle, pierces this muscle and the temporal fascia about an inch above the zygoma, and is distributed to the integument covering the temple and side of the forehead, communicating with the facial and auriculo-temporal branch of the inferior maxillary nerve. As it pierces the temporal fascia it gives off a slender twig, which runs between the two layers of the fascia to the outer angle of the orbit.

The **malar branch** passes along the external inferior angle of the orbit, emerges upon the face through a foramen in the malar bone, and, perforating the Orbicularis palpabrarum muscle, supplies the skin on the prominence of the cheek, and is named **subcutaneous malar**. It joins with the facial and the palpebral branches of the superior maxillary.

The **spheno-palatine branches**, two in number, descend to the spheno-palatine ganglion.

---

1. After it enters the infra-orbital canal, the nerve is frequently called the *infra-orbita*. 51
The posterior superior dental branches arise from the trunk of the nerve just as it is about to enter the infra-orbital canal; they are generally two in number, but sometimes arise by a single trunk, and immediately divide and pass downward on the tuberosity of the superior maxillary bone. They give off several twigs to the gums and neighboring parts of the mucous membrane of the cheek (superior gingival branches). They then enter the posterior dental canals on the zygomatic surface of the superior maxillary bone, and, passing from behind forward in the substance of the bone, communicate with the middle dental nerve, and give off branches to the lining membrane of the antrum and three twigs to each of the molar teeth. These twigs enter the foramina at the apices of the fangs and supply the pulp.

The middle superior dental branch is given off from the superior maxillary nerve in the back part of the infra-orbital canal, and runs downward and forward in a special canal in the outer wall of the antrum to supply the two bicuspid teeth. It communicates with the posterior and anterior dental branches. At its point of communication with the posterior branch is a slight thickening which has received the name of the ganglion of Valentin; and at its point of communication with the anterior branch is a second enlargement, which is called the ganglion of Bochdalek. Neither of these is probably a true ganglion.

The anterior superior dental branch, of large size, is given off from the superior maxillary nerve just before its exit from the infra-orbital foramen; it enters a special canal in the anterior wall of the antrum, and, coursing from behind backward, divides into a series of branches which supply the incisor and canine teeth. It communicates with the middle dental branch, and gives off a nasal branch, which passes through a minute canal into the nasal fossa, and supplies the mucous mem-
The palpebral branches pass upward beneath the Orbicularis palpebrarum. They supply the integument and conjunctiva of the lower eyelid with sensation, joining at the outer angle of the orbit with the facial nerve and malar branch of the orbital.

The nasal branches pass inward; they supply the integument of the side of the nose and join with the nasal branch of the ophthalmic.

The labial branches, the largest and most numerous, descend beneath the Levator labii superioris, and are distributed to the integument of the upper lip, the mucous membrane of the mouth, and labial glands.

All these branches are joined, immediately beneath the orbit, by filaments from the facial nerve, forming an intricate plexus, the *infra-orbital*.

**Spheno-palatine Ganglion (Fig. 484).**

The *spheno-palatine ganglion* (*Meckel's*), the largest of the cranial ganglia, is deeply placed in the sphenomaxillary fossa, close to the sphenopalatine foramen. It is triangular or heart-shaped, of a reddish-gray color, and is situated just below the superior maxillary nerve as it crosses the fossa.

*Its Branches of Communication.*—Like the other ganglia of the fifth nerve, it possesses a motor, a sensory, and a sympathetic root. Its *sensory root* is derived from the superior maxillary nerve through its two spheno-palatine branches. These branches of the nerve, given off in the sphenomaxillary fossa, descend to the ganglion. Their fibres, for the most part, pass in front of the ganglion, as they proceed to their destination, in the palate and nasal fossa, and are not incorporated in the ganglionic mass; some few of the fibres, however, enter the ganglion, constituting its sensory root. Its *motor root* is derived from the facial nerve through the large superficial petrosal nerve, and its *sympathetic root* from the carotid plexus, through the large deep petrosal nerve. These two nerves join together to form a single nerve, the *Vidian*, before their entrance into the ganglion.
The large superficial petrosal branch (nervus petrosus superficialis major) is given off from the intumescentia ganglioformis in the aqueductus Fallopii; it passes through the hiatus Fallopii; enters the cranial cavity, and runs forward contained in a groove on the anterior surface of the petrous portion of the temporal bone, lying beneath the dura mater and the Gasserian ganglion. It then enters the fibrous substance which fills in the foramen lacerum medium basis cranii, and, joining with the large deep petrosal branch, forms the Vidian nerve.

The large deep petrosal branch (nervus petrosus profundus) is given off from the carotid plexus, and runs through the carotid canal on the outer side of the internal carotid artery. It then enters the fibrous substance which fills in the foramen lacerum medium, and joins with the large superficial petrosal nerve to form the Vidian.

The Vidian nerve, thus formed, passes forward through the Vidian canal with the artery of the same name, receives the sphenoidal filament from the otic ganglion, and, entering the sphen-no-maxillary fossa, joins the posterior angle of Meckel's ganglion.

Its Branches of Distribution.—These are divisible into four groups: ascending, which pass to the orbit; descending, to the palate; internal, to the nose; and posterior branches, to the pharynx and nasal fossae.

The ascending branches are two or three delicate filaments which enter the orbit by the sphen-no-maxillary fissure and supply the periorbita. Arnold describes and delineates these branches as ascending to the optic nerve. Bock describes a branch as going to the cavernous sinus to communicate with the sixth nerve, and Tiedemann, a communicating branch to the ophthalmic ganglion.

The descending or palatine branches are distributed to the roof of the mouth, the soft palate, tonsil, and lining membrane of the nose. They are almost a direct continuation of the sphenopalatine branches of the superior maxillary nerve, and are three in number—anterior, middle, and posterior.

The anterior or large palatine nerve descends through the posterior palatine canal, emerges upon the hard palate at the posterior palatine foramen, and passes forward through a groove in the hard palate nearly as far as the incisor teeth. It supplies the gums, the mucous membrane and glands of the hard palate, and communicates in front with the termination of the naso-palatine nerve. While in the posterior palatine canal it gives off inferior nasal branches, which enter the nose through openings in the palate bone, and ramify over the middle meatus and the middle and inferior spongy bones; and, at its exit from the canal a palatine branch is distributed to both surfaces of the soft palate.

The middle or external palatine nerve descends through one of the accessory palatine canals, distributing branches to the uvula, tonsil, and soft palate. It is occasionally wanting.

The posterior or small palatine nerve descends with a small artery through the small posterior palatine canal, emerging by a separate opening behind the posterior palatine foramen. It supplies the Levator palati and Azygos uvulae muscles, the soft palate, tonsil, and uvula. The middle and posterior palatine join with the tonsillar branches of the glosso-pharyngeal to form the plexus around the tonsil (circulus tonsillaris).

The internal branches are distributed to the septum and outer wall of the nasal fossae. They are the superior nasal (anterior) and the nasso-palatine.

The superior nasal branches (anterior), four or five in number, enter the back part of the nasal fossa by the sphenopalatine foramen. They supply the mucous membrane covering the superior and middle spongy bones, and that lining the posterior ethmoidal cells, a few being prolonged to the upper and back part of the septum. One branch is continued on to the inner surface of the anterior wall of the antrum, and there forms a communication with the anterior dental nerve. At the point of communication a swelling exists, denominated "the ganglion of Bochdalek," the nature of which seems to be, however, uncertain.
The *naso-palatine nerve* (Cotunnius) also enters the nasal fossa through the sphenoid-palatine foramen, and passes inward across the roof of the nose, below the orifice of the sphenoidal sinus, to reach the septum; it then runs obliquely downward and forward along the lower part of the septum, to the anterior palatine foramen, lying between the periosteum and mucous membrane. It descends to the roof of the mouth through the anterior palatine canal. The two nerves are here contained in separate and distinct canals, situated in the internasal suture, and termed the foramina of Scarpa, the left nerve being usually anterior to the right one. In the mouth they become united, supply the mucous membrane behind the incisor teeth, and join with the anterior palatine nerve. The naso-palatine nerve occasionally furnishes a few small filaments to the mucous membrane of the septum.

The posterior branches are the pharyngeal (pterygo-palatine) and the upper posterior nasal branches.

The pharyngeal nerve (pterygo-palatine) is a small branch arising from the back part of the ganglion, being generally blended with the Vidian nerve. It passes through the pterygo-palatine canal with the pterygo-palatine artery, and is distributed to the mucous membrane of the upper part of the pharynx, behind the Eustachian tube.

The upper posterior nasal branches are a few twigs given off from the posterior part of the ganglion, which run backward in the sheath of the Vidian nerve to the mucous membrane at the back part of the roof, septum, and superior meatus of the nose and that covering the end of the Eustachian tube.

**Inferior Maxillary Nerve** (Fig. 483).

The Inferior Maxillary Nerve distributes branches to the teeth and gums of the lower jaw, the integument of the temple and external ear, the lower part of the face and lower lip, and the muscles of mastication; it also supplies the tongue with a large branch. It is the largest of the three divisions of the fifth, and is made up of two roots: a large or sensory root proceeding from the inferior angle of the Gasserian ganglion; and a small or motor root, which passes beneath the ganglion, and unites with the sensory root just after its exit through the foramen ovale. Immediately beneath the base of the skull this nerve divides into two trunks, anterior and posterior. Previous to its division the primary trunk gives off from its inner side a recurrent (meningeal) branch and the nerve to the Internal pterygoid muscle.

The recurrent branch is given off directly after its exit from the foramen ovale. It passes backward into the skull through the foramen spinosum with the middle meningeal artery. It divides into two branches, anterior and posterior, which accompany the main divisions of the artery and supply the dura mater. The anterior branch communicates with the meningeal branch of the superior maxillary nerve.

The Internal Pterygoid Nerve, given off from the inferior maxillary previous to its division, is intimately connected at its origin with the otic ganglion. It is a long and slender branch, which passes inward to enter the deep surface of the Internal pterygoid muscle.

The anterior and smaller division, which receives nearly the whole of the motor root, divides into branches which supply the remaining muscles of mastication. They are the masseteric, deep temporal, buccal, and external pterygoid.

The masseteric branch passes outward, above the External pterygoid muscle, in front of the temporo-maxillary articulation, and crosses the sigmoid notch with the masseteric artery to the Masseter muscle, in which it ramifies nearly as far as its anterior border. It occasionally gives a branch to the Temporal muscle and a filament to the articulation of the jaw.

The deep temporal branches supply the deep surface of the Temporal muscle. The posterior branch, of small size, is placed at the back of the temporal fossa. It is sometimes joined with the masseteric branch. The anterior branch is
reflected upward at the pterygoid ridge of the sphenoid to the front of the temporal fossa. It is often given off from the buccal branch after the latter has pierced the external pterygoid muscle. The third branch (middle deep temporal) passes outward over the External pterygoid muscle and enters the deep surface of the Temporal muscle.

The **buccal branch** passes forward between the two heads of the External pterygoid, and downward beneath the inner surface of the coronoid process of the lower jaw, or through the fibres of the Temporal muscle, to reach the surface of the Buccinator, upon which it divides into a superior and an inferior branch. It gives the branch to the External pterygoid during its passage through that muscle, and is usually joined with the anterior branch of the deep temporal nerve. The **upper branch** supplies the integument and upper part of the Buccinator muscle, joining with the facial nerve round the facial vein. The **lower branch** passes forward to the angle of the mouth: it supplies the integument and Buccinator muscle, as well as the mucous membrane lining the inner surface of that muscle, and joins the facial nerve.1

The **External Pterygoid Nerve** is most frequently derived from the buccal, but it may be given off separately from the anterior trunk of the nerve. It enters the muscle on its inner surface.

The **posterior** and larger division of the inferior maxillary nerve is for the most part sensory, but receives a few filaments from the motor root. It divides into three branches: auriculo-temporal, lingual (gustatory), and inferior dental.

The **Auriculo-temporal Nerve** generally arises by two roots, beneath which the middle meningeal artery passes. It runs backward beneath the External pterygoid muscle to the inner side of the neck of the lower jaw. It then turns upward with the temporal artery, between the external ear and condyle of the jaw, under cover of the parotid gland, and, escaping from beneath this structure, ascends over the zygoma and divides into two temporal branches.

The **branches of communication** are with the facial and with the otic ganglion. The branches of communication with the facial, usually two in number, pass forward from behind the neck of the condyle of the jaw, to join the temporo-facial division of this nerve at the posterior border of the Masseter muscle. They form one of the principal branches of communication between the facial and the fifth nerve. The filaments of communication with the otic ganglion are derived from the commencement of the auriculo-temporal nerve.

The **branches of distribution** are—

<td></td>
</tr>
</tbody>
</table>

The **inferior auricular** arises behind the articulation of the jaw, and is distributed to the ear below the external meatus: other filaments twine round the internal maxillary artery and communicate with the sympathetic. The **superior auricular** arises in front of the external ear, and supplies the integument covering the tragus and pinna.

**Branches to the meatus auditory**: upper and lower, arise from the point of communication between the auriculo-temporal and facial nerves, and are distributed to the meatus. A filament from the upper passes to the membrana tympani.

A **branch to the temporo-maxillary articulation** is usually derived from the auriculo-temporal nerve.

The **parotid branches** supply the parotid gland.

The **anterior temporal** accompanies the temporal artery to the vertex of the skull, and supplies the integument of the temporal region, communicating with the facial nerve and the temporal branch of the temporo-malar from the superior

---

1 There seems to be no reason to doubt that the branch supplying the Buccinator muscle is entirely a nerve of ordinary sensation, and that the true motor-supply of this muscle is from the facial.
maxillary. The *posterior temporal*, the smaller of the two, is distributed to the upper part of the pinna and the neighboring tissues.

The **Lingual Nerve (gustatory)** supplies the papillae and mucous membrane of the tongue. It is deeply placed throughout the whole of its course. It lies at first beneath the External pterygoid muscle, together with the inferior dental nerve, being placed to the inner side of the latter nerve, and is occasionally joined to it by a branch which crosses the internal maxillary artery. The chorda tympani also joins it at an acute angle in this situation. The nerve then passes between the Internal pterygoid muscle and the inner side of the ramus of the jaw, and crosses obliquely to the side of the tongue over the Stylo-glossus muscle, and then between the Hyo-glossus muscle and deep part of the submaxillary gland: the nerve lastly runs across Wharton's duct, and along the side of the tongue to its apex, lying immediately beneath the mucous membrane.

The branches of communication are with the facial through the chorda tympani, the inferior dental and hypoglossal nerves, and the submaxillary ganglion. The branches to the submaxillary ganglion are two or three in number; those connected with the hypoglossal nerve form a plexus at the anterior margin of the Hyo-glossus muscle.

The branches of distribution are few in number. They supply the mucous membrane of the mouth, the gums, and the sublingual gland, while the lingual or terminal branches supply the mucous membrane of the tongue over its anterior two-thirds, terminating in the filiform and fungiform papillae.

The **Inferior Dental** is the largest of the three branches of the inferior maxillary nerve. It passes downward with the inferior dental artery, at first beneath the External pterygoid muscle, and then between the internal lateral ligament and the ramus of the jaw to the dental foramen. It then passes forward in the dental canal of the inferior maxillary bone, lying beneath the teeth, as far as the mental foramen, where it divides into two terminal branches, incisor and mental.

The branches of the inferior dental are, the mylo-hyoid, dental, incisive, and mental.

The **mylo-hyoid** is derived from the inferior dental just as that nerve is about to enter the dental foramen. It descends in a groove on the inner surface of the ramus of the jaw, in which it is retained by a process of fibrous membrane. It reaches the under surface of the Mylo-hyoid muscle, and supplies it and the anterior belly of the Digastric, occasionally sending one or two filaments to the submaxillary gland.

The **dental branches** supply the molar and bicuspid teeth. They correspond in number to the fangs of those teeth: each nerve entering the orifice at the point of the fang and supplying the pulp of the tooth.

The **incisive branch** is continued onward within the bone to the middle line, and supplies the canine and incisor teeth.

The **mental branch** emerges from the bone at the mental foramen, and divides beneath the Depressor anguli oris into two or three branches; one descends to supply the skin of the chin, and another (sometimes two) ascends to supply the skin and mucous membrane of the lower lip. These branches communicate freely with the facial nerve.

Two small ganglia are connected with the inferior maxillary nerve—the otic with the trunk of the nerve, and the submaxillary with its lingual branch.

**Otic Ganglion** (Fig. 485).

The **Otic Ganglion (Arnold's)** is a small, oval-shaped, flattened ganglion of a reddish-gray color, situated immediately below the foramen ovale, on the inner surface of the inferior maxillary nerve, and round the origin of the internal pterygoid nerve. It is in relation, externally, with the trunk of the inferior maxillary nerve, at the point where the motor root joins the sensory portion; internally, with the cartilaginous part of the Eustachian tube, and the origin of the Tensor palati muscle; behind it is the middle meningeal artery.
Branches of Communication.—This ganglion is connected with the internal pterygoid branch of the inferior maxillary nerve by two or three short, delicate filaments. From this it may obtain a motor root, and possibly also a sensory root, as these filaments from the nerve to the Internal pterygoid may contain sensory fibres. It communicates with the glosso-pharyngeal and facial nerves through the small superficial petrosal nerve continued from the tympanic plexus (pages 811 and 818), and through this communication it probably receives its sensory root from the glosso-pharyngeal and its motor root from the facial; its communication with the sympathetic is effected by a filament from the plexus surrounding the middle meningeal artery. The ganglion also communicates with the auriculo-temporal nerve. This is probably a branch from the glosso-pharyngeal which passes to the ganglion, and through it and the auriculo-temporal nerve to the parotid gland. The sphenoidal filament joins the Vidian nerve.

Its branches of distribution are a filament to the Tensor tympani and one to the Tensor palati. The former passes backward on the outer side of the Eustachian tube; the latter arises from the ganglion, near the origin of the internal pterygoid nerve, and passes forward. The fibres of these nerves are, however, mainly derived from the nerve to the Internal pterygoid muscle. It also gives off a small communicating branch to the chorda tympani and one to the buccal nerve (Rauber).

Submaxillary Ganglion (Fig. 483).

The submaxillary ganglion is of small size, fusiform in shape, and situated above the deep portion of the submaxillary gland, near the posterior border of the Mylo-hyoid muscle, being connected by filaments with the lower border of the lingual (gustatory) nerve.

Branches of Communication.—This ganglion is connected with the lingual (gustatory) nerve by a few filaments which join it separately at its fore and back part. It also receives a branch from the chorda tympani, by which it communicates with the facial, and communicates with the sympathetic by filaments from the sympathetic plexus around the facial artery.

Branches of Distribution.—These are five or six in number: they arise from the lower part of the ganglion, and supply the mucous membrane of the mouth and...
Wharton's duct, some being lost in the submaxillary gland. The branch of communication from the lingual to the fore part of the ganglion is by some regarded as a branch of distribution, by which filaments of the chorda tympani pass from the ganglion to the nerve, and by it are conveyed to the sublingual gland and the tongue.

Surface Marking.—It will be seen from the above description that the three terminal branches of the three divisions of the fifth nerve emerge from foramina in the bones of the skull and face on to the face: the terminal branch of the first division emerging through the supra-orbital foramen; that of the second through the infra-orbital foramen; and the third through the mental foramen. The supra-orbital foramen is situated at the junction of the internal and middle third of the supra-orbital arch between the internal and external angular processes. If a straight line is drawn from this point to the lower border of the inferior maxillary bone, so that it passes between the two bicuspids teeth in both jaws, it will pass over the infra-orbital nerve, and through the mental foramen, the former being situated about one centimetre (two-fifths of an inch) below the margin of the orbit, and the latter varying in position according to the age of the individual. In the adult it is midway between the upper and lower borders of the inferior maxillary bone; in the child it is nearer the lower border; and in the edentulous jaw of old age it is close to the upper margin.

Surgical Anatomy.—The fifth nerve may be affected in its entirety, or its sensory or motor root may be affected, or one of its primary main divisions. In injury to the sensory root there is anaesthesia of the whole of the side of the face on the side of the lesion, with the exception of the skin over the parotid gland; insensibility of the conjunctiva, followed by destructive inflammation of the cornea, partly from loss of trophic influence, and partly from the irritation produced by the presence of foreign bodies on it, which are not perceived by the patient, and therefore not expelled by the act of winking; dryness of the nose, loss to a considerable extent of the sense of taste, and diminished secretion of the lachrymal and salivary glands. In injury to the motor root there is impaired action of the lower jaw from paralysis of the muscles of mastication on the affected side.

The fifth nerve is often the seat of neuralgia, and each of its three divisions has been divided or a portion of the nerve excised for this affection. The supra-orbital nerve may be exposed by making an incision an inch and a half in length along the supra-orbital margin below the eyebrow, which is to be drawn upward, the centre of the incision corresponding to the supra-orbital notch. The skin and Orbicularis palpabrum having been divided, the nerve can be easily found emerging from the notch and lying in loose cellular tissue. It should be drawn up by a blunt hook and divided, or, what is better, a portion of it removed. The infra-orbital nerve has been divided at its exit by an incision on the cheek; or the floor of the orbit has been exposed, the infra-orbital canal opened up, and the anterior part of the nerve resected; or the whole nerve, together with Meckel's ganglion as far back as the foramen rotundum, has been removed. This latter operation, though undoubtedly a severe proceeding, appears to have been followed by the best results. The operation is performed as follows: The superior maxillary bone is first exposed by a T-shaped incision, one limb passing along the lower margin of the orbit, the other from the centre of this vertically down the cheek to the angle of the mouth. The nerve is then found, divided, and a piece of silk tied to it as a guide. A small trephine (one-half inch) is then applied to the bone below, but including, the infra-orbital foramen, and the antrum opened. The trephine is now applied to the posterior wall of the antrum, and the sphen-maxillary fossa exposed. The infra-orbital canal is now opened up below from a piece of silk tied to it, being held on the stretch by means of the piece of silk; it is severed with fine curved scissors as near the foramen rotundum as possible, any branches coming off from the ganglion being also divided. The inferior dental nerve has been divided at its exit from the foramen by an incision made through the mucous membrane where it is reflected from the alveolar process on to the lower lip; or a portion of the nerve has been resected by an incision on the cheek through the Masseter muscle, exposing the outer surface of the ramus of the jaw. A trephine was then applied over the position of the inferior dental foramen and the outer table removed, so as to expose the inferior dental canal. The nerve was dissected out of the portion of the canal exposed, and, having been divided after its exit from the mental foramen, it was tracted on the end exposed in the trephine hole, drawn out entire, and cut off as high up as possible. The inferior dental nerve has also been divided by an incision within the mouth, the bony point guarding the inferior dental foramen forming the guide to the nerve. The buccal nerve may be divided by an incision through the mucous membrane of the mouth and the Bucinator just in front of the anterior border of the ramus of the lower jaw (Stimson).

The lingual (gustatory) nerve is occasionally divided with the view of relieving the pain in cancerous disease of the tongue. This may be done in that part of its course where it lies below and behind the last molar tooth. If a line is drawn from the middle of the crown of the last molar tooth to the angle of the jaw, it will cross the nerve, which lies about half an inch behind the tooth, parallel to the bulging alveolar ridge on the inner side of the body of the bone. If the knife is entered three-quarters of an inch behind and below the last molar tooth and carried

down to the bone, the nerve will be divided. Hilton divided it opposite the second molar tooth, where it is covered only by the mucous membrane, and Lucas pulls the tongue forward and over to the opposite side, when the nerve can be seen standing out as a firm cord under the mucous membrane by the side of the tongue, and can be easily seized with a sharp hook and divided or a portion excised. This is a simple enough operation on the cadaver, but when the disease is extensive and has extended to the floor of the mouth, as is generally the case when division of the nerve is required, the operation is not practicable.

**Sixth Nerve** (Figs. 384, 481).

The Sixth or Abducens Nerve supplies the External rectus muscle. Its superficial origin is by several filaments from the constricted part of the pyramid close to the pons, or from the lower border of the pons itself in the groove between this body and the medulla. Its deep origin is a little lower than the motor root of the fifth, and close to the median line, beneath the superior portion (above the auditory striae) of the fasciculus teres on the floor of the fourth ventricle.

The nerve pierces the dura mater on the basilar surface of the sphenoid bone, runs through a notch immediately below the posterior clinoid process, and enters the cavernous sinus. It passes forward through the sinus, lying on the outer side of the internal carotid artery. It enters the orbit through the sphenoidal fissure, and lies above the ophthalmic vein, from which it is separated by a lamina of dura mater. It then passes between the two heads of the External rectus, and is distributed to that muscle on its ocular surface.

*Branches of Communication.*—It is joined by several filaments from the carotid and cavernous plexus, by one from Meckel's ganglion (Bock), and another from the ophthalmic nerve.

The above-mentioned nerve, as well as the third, fourth, and the ophthalmic division of the fifth, as they pass to the orbit, bear a certain relation to each other in the cavernous sinus, at the sphenoidal fissure, and in the cavity of the orbit, which will now be described.

In the cavernous sinus (Fig. 384) the third, fourth, and ophthalmic division of the fifth are placed on the outer wall of the sinus, in their numerical order both from above downward and from within outward. The sixth nerve lies at the outer side of the internal carotid artery. As these nerves pass forward to the sphenoidal fissure, the third and fifth nerves become divided into branches, and the sixth approaches the rest, so that their relative position becomes considerably changed.

In the sphenoidal fissure (Fig. 486) the fourth and the frontal and lachrymal divisions of the ophthalmic lie upon the same plane, the former being most internal, the latter external, and they enter the cavity of the orbit above the muscles. The remaining nerves enter the orbit between the two heads of the External rectus. The superior division of the third is the highest of these; beneath this lies the nasal branch of the ophthalmic; then the inferior division of the third; and the sixth lowest of all.
In the orbit the fourth and the frontal and lachrymal divisions of the ophthalmic lie on the same plane immediately beneath the periosseum, the fourth nerve being internal and resting on the Superior oblique, the frontal resting on the Levator palpebrae, and the lachrymal on the External rectus. Next in order comes the superior division of the third nerve, lying immediately beneath the Superior rectus, and then the nasal branch of the ophthalmic, crossing the optic nerve from the outer to the inner side of the orbit. Beneath these is found the optic nerve, surrounded in front by the ciliary nerves, and having the lenticular ganglion on its outer side, between it and the External rectus. Below the optic is the inferior division of the third and the sixth, which lies on the outer side of the orbit.

Surgical Anatomy.—The sixth nerve is more frequently involved in fractures of the base of the skull than any other of the cranial nerves. The result of paralysis of this nerve is internal or convergent squint. When injured so that its function is destroyed, there is, in addition to the paralysis of the External rectus muscle, often a certain amount of contraction of the pupil, because some of the sympathetic fibres to the radiating muscle of the iris pass along with this nerve.

Seventh Nerve (Figs. 487 and 489).—The Seventh or Facial Nerve (portio dura) is the motor nerve of all the muscles of expression in the face and of the Platysma and Buccinator, the muscles of the External ear, the posterior belly of the Digastric, and the Stylohyoid. Through its chorda tympani it supplies the Linguales; by its tympanic branch the Stapedius. Its superficial origin is from the upper end of the medulla oblongata, in the groove between the olivary and restiform bodies. Its deep origin is from a nucleus in the pons, below the floor of the fourth ventricle, somewhat ventral and external to the nucleus of the sixth nerve.

The auditory nerve (portio mollis) lies to its outer side, and between the two is a small fasciculus (portio inter duram et mollem of Wrigberg, or pars intermedia), which arises from the medulla and joins the facial nerve in the internal auditory meatus. At its origin it is frequently connected with both the nerves between which it lies.

The facial nerve, firmer, rounder, and smaller than the auditory, passes forward and outward together with that nerve, and with it enters the internal auditory meatus. Within the meatus the facial nerve lies in a groove along the upper and anterior part of the auditory nerve. The pars intermedia is placed between the facial and auditory nerves in the internal auditory meatus; a few of its fibres frequently pass into the auditory nerve, while the remainder join the facial. At the bottom of the meatus it is connected to this nerve by one or two slender filaments.

At the bottom of the meatus the facial nerve enters the aqueductus Fallopii, and follows the serpentine course of that canal through the petrous portion of the temporal bone, from its commencement at the internal meatus to its termination at the stylo-mastoid foramen. It is at first directed outward toward the inner wall of the tympanum, where it forms a reddish gangliform swelling (intumescentia ganglioformis, or geniculate ganglion), and is joined by several nerves; then bending suddenly backward, it runs in the internal wall of the tympanum, above the fenestra ovalis, and at the back of that cavity passes vertically downward behind the tympanum to the stylo-mastoid foramen. On emerging from this aperture it runs forward in the substance of the parotid gland, crosses the external carotid artery, and divides behind the ramus of the lower jaw into two primary branches, temporo-facial and cervico-facial, from which numerous offsets are distributed over
the side of the head, face, and upper part of the neck, supplying the superficial muscles in these regions. As the primary branches and their offsets diverge from each other they present somewhat the appearance of a bird’s claw; hence the name of \textit{pes anserinus} is given to the divisions of the facial nerve in and near the parotid gland.

The branches of communication of the facial nerve may be thus arranged:

In the internal auditory meatus . . . . With the auditory nerve.

With Meckel’s ganglion by the large superficial petrosal nerve.

With the otic ganglion by the small superficial petrosal nerve.

In the aqueductus Fallopii

With the sympathetic on the middle meningeal by the external superficial petrosal nerve.

With the auricular branch of the pneumogastric.

With the glosso-pharyngeal (Digastric).

After its exit from the stylo-mastoid foramen

With the pneumogastric (Posterior auricular).

With the carotid plexus (Stylo-hyoid).

With the auricularis magnus (Posterior auricular).

With the auriculo-temporal (Temporal).

With the three divisions of the fifth.

On the face . . . .

In the internal auditory meatus some minute filaments pass between the facial and auditory nerves.

Opposite the hiatus Fallopii the gangliform enlargement on the facial nerve communicates with Meckel’s ganglion by means of the large superficial petrosal nerve, which forms its motor root; with the otic ganglion, by the small superficial petrosal nerve; and with the sympathetic filaments accompanying the middle meningeal artery, by the external petrosal (Bidder). From the gangliform enlargement, according to Arnold, a twig is sent back to the auditory nerve.

Just before leaving the aqueduct a twig joins the auricular branch of the pneumogastric nerve.

Just after its exit from the stylo-mastoid foramen it communicates with the following nerves by means of its respective branches: With the auricular branch of the pneumogastric and auricularis magnus of the cervical plexus, by the Posterior auricular branch; with the glosso-pharyngeal, by the digastric; with the carotid plexus, by the stylo-hyoid; and with the auriculo-temporal, by its temporal branches.

\textbf{Branches of Distribution.}

\begin{itemize}
  \item Within the aqueductus Fallopii
    \begin{itemize}
      \item Tympanic.
      \item Chorda Tympani.
      \item Posterior Auricular.
      \item Digastric.
      \item Stylo-hyoid.
    \end{itemize}
  \item At its exit from the stylo-mastoid foramen
    \begin{itemize}
      \item Temporofacial
        \begin{itemize}
          \item Temporal.
          \item Malar.
          \item Infra-orbital.
          \item Buccal.
        \end{itemize}
      \item Cervico-facial
        \begin{itemize}
          \item Supramaxillary.
          \item Inframaxillary.
        \end{itemize}
    \end{itemize}
  \item On the face
\end{itemize}

The \textbf{tympanic branch} arises from the nerve opposite the pyramid; it passes through a small canal in the pyramid and supplies the \textit{Stapedius} muscle.

The \textbf{chorda tympani} is given off from the facial as it passes vertically down-
ward at the back of the tympanum, about a quarter of an inch before its exit from the stylo-mastoid foramen. It passes from below upward and forward in a
distinct canal, and enters the cavity of the tympanum through an aperture (*iter chordae posterior*) on its posterior wall between the opening of the mastoid cells and the attachment of the membrana tympani, and becomes invested with mucous membrane. It passes forward through the cavity of the tympanum, between the handle of the malleus and vertical ramus of the incus, to its anterior inferior angle, and emerges from that cavity through a foramen at the inner end of the Glaserian fissure, which is called the *iter chordae anterius*, or canal of Hugrier. It then descends between the two Pterygoid muscles, meets the lingual nerve at an acute angle, and accompanies it to the submaxillary gland; part of it then joins the submaxillary ganglion; the rest is continued onward into the proper muscular fibres of the tongue—the Inferior lingualis muscle. A few of its fibres probably pass through the submaxillary ganglion to the sublingual gland. Before joining the lingual nerve it receives a small communicating branch from the otic ganglion.

The *Posterior auricular nerve* arises close to the stylo-mastoid foramen, and passes upward in front of the mastoid process, where it is joined by a filament from the auricular branch of the pneumogastric, and communicates with the mastoid branch of the auricularis magnus and with the small occipital. As it ascends between the meatus and mastoid process it divides into two branches. The *auricular branch* supplies the Retrahens aurem and the small muscles on the cranial surface of the pinna. The *occipital branch*, the larger, passes backward along the superior curved line of the occipital bone, and supplies the occipital portion of the Occipito-frontalis.

The *digastric branch* usually arises by a common trunk with the Stylo-hyoid branch; it divides into several filaments, which supply the posterior belly of the Digastric; one of these perforates that muscle to join the glosso-pharyngeal nerve.

The *stylo-hyoid* is a long slender branch, which passes inward, entering the Stylo-hyoid muscle about its middle; it communicates with the sympathetic filaments on the external carotid artery.

The *Temporo-facial*, the larger of the two terminal branches, passes upward and forward through the parotid glands, crosses the external carotid artery and
temporo-maxillary vein, and passes over the neck of the condyle of the jaw, being connected in this situation with the auriculo-temporal branch of the inferior maxillary nerve, and divides into branches which are distributed over the temple and upper part of the face; these are divided into three sets—temporal, malar, and infra-orbital.

The temporal branches cross the zygoma to the temporal region, supplying the Attrahens and Attollens aurem muscles, and join with the temporal branch of the temporo-malar, a branch of the superior maxillary, and with the auriculo-temporal branch of the inferior maxillary. The more anterior branches supply the frontal portion of the Occipito-frontalis, the Orbicularis palpebrarum, and Corrugator supercili muscles, joining with the supra-orbital and lachrymal branches of the ophthalmic.

The malar branches pass across the malar bone to the outer angle of the orbit, where they supply the Orbicularis palpebrarum muscle, joining with filaments from the lachrymal nerve; others supply the lower eyelid, joining with filaments of the malar branch (subcutaneus mala) of the superior maxillary nerve.

The infra-orbital, of larger size than the rest, pass horizontally forward to be distributed between the lower margin of the orbit and the mouth. The superficial branches run beneath the skin and above the superficial muscles of the face, which they supply: some branches are distributed to the Pyramidalis nasi, joining at the

---

**Fig. 489.—The nerves of the scalp, face, and side of the neck.**
inner angle of the orbit with the infratrochlear and nasal branches of the ophthalmic. The deep branches pass beneath the Zygomatici and the Levator labii superioris, supplying them and the Levator anguli oris, and form a plexus (infracarotid) by joining with the infra-orbital branch of the superior maxillary nerve and the buccal branches of the cervico-facial. This branch also supplies the Levator labii superioris alaeque nasi and the small muscles of the nose.

The Cervico-facial division of the facial nerve passes obliquely downward and forward through the parotid gland, crossing the external carotid artery. In this situation it is joined by branches from the great auricular nerve. Opposite the angle of the lower jaw it divides into branches which are distributed on the lower half of the face and upper part of the neck. These may be divided into three sets—buccal, supramaxillary, and inframaxillary.

The buccal branches cross the Masseter muscle. They supply the Buccinator and Orbicularis oris, and join with the infra-orbital branches of the tempo-facial division of the nerve, and with filaments of the buccal branch of the inferior maxillary nerve.

The supramaxillary or mandibular branches pass forward beneath the Platysma and Depressor anguli oris, supplying the muscles of the lower lip and chin, and communicating with the mental branch of the inferior dental nerve.

The inframaxillary or cervical branches run forward beneath the Platysma, and form a series of arches across the side of the neck over the suprathyroid region. One of these branches descends vertically to join with the superficialis colli nerve from the cervical plexus; others supply the Platysma.

Surgical Anatomy.—The facial nerve is more frequently paralyzed than any of the other of the cranial nerves. The paralysis may depend either upon (1) central causes—i.e., blood-clots or intracranial tumors pressing on the nerve before its entrance into the internal auditory meatus. It is also one of the nerves involved in “bulbar paralysis.” Or (2) it may be paralyzed in its passage through the petrous bone by damage due to middle-ear disease or by fractures of the base. Or (3) it may be affected at or after its exit from the stylo-mastoid foramen. This is commonly known as “Bell’s paralysis.” It may be due to exposure to cold or to injury of the nerve, either from accidental wounds of the face or during some surgical operation, as removal of parotid tumors, opening of abscesses, or operations on the lower jaw.

The facial nerve is at fault in cases of so-called “histronic spasm,” which consists in an almost constant and uncontrollable twitching of the muscles of the face. This twitching is sometimes so severe as to cause great discomfort and annoyance to the patient and to interfere with sleep, and for its relief the facial nerve has been stretched. The operation is performed by making an incision behind the ear from the root of the mastoid process to the angle of the jaw. The parotid is turned forward, and the dissection carried along the anterior border of the Sterno-mastoid muscle and mastoid process until the upper border of the posterior belly of the Digastric is found. The nerve is parallel to this on about a level of the middle of the mastoid process. When found, the nerve must be stretched by passing a blunt hook beneath it and pulling it forward and outward. Too great force must not be used, for fear of permanent injury to the nerve.

Eighth Nerve.

The Eighth or Auditory Nerve (portio mollis) is the special nerve of the sense of hearing, being distributed exclusively to the internal ear.

Its superficial origin is by two roots. One, the mesial, is from the groove between the olivary and restiform bodies at the lower border of the pons. The other, or lateral root, winds around the upper end of the restiform body, dorsally, and joins the former at its exit in the groove. This root is apparently continuous with the auditory striae. The nerve, thus formed, lies external to the facial nerve. Each root has a deep origin: 1. The mesial root is traceable dorsally, through the substance of the medulla, lying close to the mesial or attached surface of the restiform body, to the dorsal auditory nucleus, which lies immediately ventral to a prominence, the acoustic tubercle, on the outer side of the inferior fovea on the floor of the fourth ventricle. 2. The fibres of the lateral root are traceable dorsally to four different sources: (a) To the accessory or ventral auditory nucleus, which lies close in front of the restiform body and between this root and the mesial; (b) to its own ganglion, or ganglion of the lateral root, situated among the fibres where they bend around the restiform body; (c) to the auditory striae;
and (d) trapezium of the pons. The first-mentioned origin, however, gives most of the fibres (see Fig. 488). The auditory nerve passes forward across the posterior border of the middle peduncle of the cerebellum, in company with the facial nerve, from which it is partially separated by a small artery (auditory). It then enters the internal auditory meatus, with the facial nerve in a groove along its upper and fore part. At the bottom of the meatus it receives one or two filaments from the facial nerve, and then divides into two branches, cochlear and vestibular. The auditory nerve is soft in texture (hence the name portio mollis), and is destitute of neurilemma. The distribution of the auditory nerve in the internal ear will be found described along with the anatomy of that organ in a subsequent page.

Surgical Anatomy.—The auditory nerve is frequently injured, together with the facial nerve, in fractures of the middle fossa of the base of the skull implicating the internal auditory meatus. The nerve may be either torn across, producing permanent deafness, or it may be bruised or pressed upon by extravasated blood or inflammatory exudation, when the deafness will in all probability be temporary. The nerve may also be injured by violent blows on the head without fracture, and deafness may arise from loud explosions from dynamite, etc., probably from some lesion of this nerve, which is more liable to be injured than the other cranial nerves on account of its structure. The test that the nerve is destroyed and that the deafness is not due to some lesion of the auditory apparatus is obtained by placing a vibrating tuning-fork on the head. The vibrations will be heard in cases where the auditory apparatus is at fault, but not in cases of destruction of the auditory nerve.

Ninth Pair (Figs. 490, 491, 492).

The Ninth or Glossopharyngeal Nerve is distributed, as its name implies, to the tongue and pharynx, being the nerve of sensation to the mucous membrane of the pharynx, fauces, and tonsil, and a special nerve of taste to all the parts of the tongue to which it is distributed. Its superficial origin is by three or four filaments closely connected together, from the upper part of the medulla oblongata, in the groove between the olivary and the restiform body.

Its deep origin may be traced through the fasciculi which lie between the lateral and posterior areas of the medulla to a nucleus of gray matter in the lower part of the floor of the fourth ventricle, beneath the inferior fovea, above the nucleus of the pneumogastric. From its superficial origin it passes outward across the flocculus, and leaves the skull at the central part of the jugular foramen, in a separate sheath of the dura mater, external to and in front of the pneumogastric and spinal accessory nerves (Fig. 386). In its passage through the jugular foramen it grooves the lower border of the petrous portion of the temporal bone, and at its exit from the skull passes forward between the jugular vein and internal carotid artery, and descends in front of the latter vessel, and beneath the styloid process and the muscles connected with it. to the lower border of the Stylo-pharyngeus. The nerve now curves inward, forming an arch on the side of the neck, and lying upon the Stylo-pharyngeus and Middle constrictor of the pharynx, above the superior laryngeal nerve. It then passes beneath the Hyoglossus, and is finally distributed to the mucous membrane of the fauces and base of the tongue, and the mucous glands of the mouth and tonsil.

In passing through the jugular foramen the nerve presents, in succession, two gangliform enlargements. The superior, the smaller, is called the jugular ganglion; the inferior and larger, the petrous ganglion, or the ganglion of Anderseh.

The superior, or jugular, ganglion is situated in the upper part of the groove in which the nerve is lodged during its passage through the jugular foramen. It is of very small size, and involves only the lower part of the trunk of the nerve. It is usually regarded as a segmentation from the lower ganglion.
The inferior, or petrous, ganglion is situated in a depression in the lower border of the petrous portion of the temporal bone; it is larger than the former and...
involves the whole of the fibres of the nerve. From this ganglion arise those filaments which connect the glosso-pharyngeal with the pneumogastric and sympathetic nerves.

The branches of communication are with the pneumogastric, sympathetic, and facial.

The branches to the pneumogastric are two filaments, arising from the petrous ganglion, one to its auricular branch, and one to the upper ganglion of the pneumogastric.

The branch to the sympathetic, also arising from the petrous ganglion, is connected with the superior cervical ganglion.

The branch of communication with the facial perforates the posterior belly of the Digastric. It arises from the trunk of the nerve below the petrous ganglion, and joins the digastric branch of the facial (see page 813).

The branches of distribution are the tympanic, carotid, pharyngeal, muscular, tonsillar, and lingual.

The tympanic branch (Jacobson's nerve) arises from the petrous ganglion, and enters a small bony canal in the lower surface of the petrous portion of the temporal bone, the lower opening of which is situated on the bony ridge which separates the carotid canal from the jugular fossa. It ascends to the tympanum, enters that cavity by an aperture in its floor close to the inner wall, and divides into branches which are contained in grooves upon the surface of the promontory, forming the tympanic plexus.

Its branches of distribution are—one to the fenestra rotunda, one to the fenestra ovalis, and one to the lining membrane of the tympanum and Eustachian tube.

Its branches of communication are three, and occupy separate grooves on the surface of the promontory. One, the small deep petrosal, arches forward and downward to the carotid canal (piercing the bone) to join the carotid plexus. A second, the long petrosal nerve, runs forward through a canal in the processus cochleariformis and enters the foramen lacerum medium, where it joins the carotid plexus of the sympathetic, and generally the large superficial petrosal nerve. The third branch runs upward through the substance of the petrous portion of the temporal bone. In its course it passes by the gangliform enlargement of the facial nerve, and, receiving a connecting filament from it, becomes the small superficial petrosal nerve. This nerve enters the skull through a small aperture situated external to the hiatus Fallopii on the anterior surface of the petrous bone, courses forward across the base of the skull, and emerges through the petro-sphenoidal fissure or a foramen in the great wing of the sphenoid, and joins the otic ganglion.

The carotid branches descend along the trunk of the internal carotid artery as far as its commencement, communicating with the pharyngeal branch of the pneumogastric and with branches of the sympathetic.

The pharyngeal branches are three or four filaments which unite opposite the Middle constrictor of the pharynx with the pharyngeal branches of the pneumogastric, the external laryngeal, and sympathetic nerves to form the pharyngeal plexus, branches from which perforate the muscular coat of the pharynx to supply the muscles and mucous membrane.

The muscular branch is distributed to the Stylo-pharyngeus.

The tonsillar branches supply the tonsil, forming a plexus (circulus tonsillaris) around this body, from which branches are distributed to the soft palate and fauces, where they communicate with the palatine nerves.

The lingual branches (terminal) are two: one supplies the circumvallate papillae, the mucous membrane covering the base of the tongue, and the anterior surface of the epiglottis; the other supplies the mucous membrane of the side of the tongue for about one-half its length.
THE TENTH OR PNEUMOGASTRIC NERVE.

Tenth Pair (Figs. 491, 492).

The Tenth or Pneumogastric Nerve (nervus vagus or par vagum) has a more extensive distribution than any of the other cranial nerves, passing through the neck and thorax to the upper part of the abdomen. It is composed of both motor and sensory fibres. It supplies the organs of voice and respiration with motor and sensory fibres, and the pharynx, oesophagus, stomach, and heart with motor fibres. Its superficial origin is by eight or ten filaments from the groove between the olivary and the restiform body below the glosso-pharyngeal; its deep origin may be traced through the fasciculi of the medulla to its nucleus of gray matter in the lower part of the floor of the fourth ventricle beneath the ala cinerea below and continuous with the nucleus of origin of the glosso-pharyngeal. The filaments become united and form a flat cord, which passes outward beneath the flocculus to the jugular foramen, through which it emerges from the cranium. In passing through this opening the pneumogastric accompanies the spinal accessory, being contained in the same sheath of dura mater with it, a membranous septum separating it from the glosso-pharyngeal, which lies in front (Fig. 386). The nerve in this situation presents a well-marked ganglionic enlargement, which is called the jugular ganglion, or the ganglion of the root of the pneumogastric: to it the accessory part of the spinal accessory nerve is connected by one or two filaments. After the exit of the nerve from the jugular foramen the nerve is joined by the accessory portion of the spinal accessory, and enlarged into a second ganglionic swelling, called the ganglion inferior, or the ganglion of the trunk of the nerve, over which the fibres of the spinal accessory pass unchanged, being principally distributed to the pharyngeal and superior laryngeal branches of the vagus; but some of the filaments from it are continued into the trunk of
the vagus below the ganglion, to be distributed with the recurrent laryngeal nerve, and probably also with the cardiac nerves. The nerve passes vertically down the neck within the sheath of the carotid vessels lying between the internal carotid artery and internal jugular vein as far as the thyroid cartilage, and then between the same vein and the common carotid to the root of the neck. Here the course of the nerve becomes different on the two sides of the body.

On the right side the nerve passes across the subclavian artery between it and the right innominate vein, and descends by the side of the trachea to the back part of the root of the lung, where it spreads out in a plexiform network (posterior pulmonary), from the lower part of which two cords descend upon the oesophagus, on which they divide, forming, with branches from the opposite nerve, the oesophageal plexus (plexus gulae); below, these branches are collected into a single cord, which runs along the back part of the oesophagus, enters the abdomen, and is distributed to the posterior surface of the stomach, joining the left side of the solar plexus, and sending filaments to the splenic plexus and a considerable branch to the coeliac plexus.

On the left side the pneumogastric nerve enters the chest between the left carotid and subclavian arteries, behind the left innominate vein. It crosses the arch of the aorta and descends behind the root of the left lung, forming the posterior pulmonary plexus, and along the anterior surface of the oesophagus, where it unites with the nerve of the right side in forming the plexus gulae, to the stomach, distributing branches over its anterior surface, some extending over the great cul-de-sac, and others along the lesser curvature. Filaments from these branches enter the gastro-hepatic omentum and join the hepatic plexus.

The ganglion of the root is of a grayish color, circular in form, about two lines in diameter, and resembles the ganglion on the large root of the fifth nerve.

Connecting Branches.—To this ganglion the accessory portion of the spinal accessory nerve is connected by several delicate filaments; it also has a communicating twig with the petrous ganglion of the glossopharyngeal, with the facial nerve by means of its (the ganglion's) auricular branch, and with sympathetic by means of an ascending filament from the superior cervical ganglion.

The ganglion of the trunk (inferior) is a plexiform cord, cylindrical in form, of a reddish color, and about an inch in length; it involves the whole of the fibres of the nerve, and passing through it is the accessory portion of the spinal accessory nerve, which blends with the pneumogastric below the ganglion, and is then principally continued into its pharyngeal and superior laryngeal branches.

Connecting Branches.—This ganglion is connected with the hypoglossal, the superior cervical ganglion of the sympathetic, and the loop between the first and second cervical nerves.

The branches of the pneumogastric are—

- **In the jugular fossa**
  - Meningeal
  - Auricular
  - Pharyngeal
  - Superior laryngeal
  - Recurrent laryngeal
  - Cervical cardiac
  - Thoracic cardiac
  - Anterior pulmonary
  - Posterior pulmonary
  - Oesophageal
  - Gastric

The **meningeal branch** is a recurrent branch given off from the ganglion of the root in the jugular foramen. It passes backward, and is distributed to the dura mater covering the posterior fossa of the base of the skull.
The auricular branch (Arnold's) arises from the ganglion of the root, and is joined soon after its origin by a filament from the petrous ganglion of the glossopharyngeal; it passes outward behind the jugular vein, and enters a small canal on the outer wall of the jugular fossa. Traversing the substance of the temporal bone, it crosses the aqueductus Fallopii about two lines above its termination at the stylo-mastoid foramen; here it gives off an ascending branch, which joins the facial: the continuation of the nerve reaches the surface by passing through the auricular fissure between the mastoid process and the external auditory meatus, and divides into two branches, one of which communicates with the posterior auricular nerve, while the other supplies the integument at the back part of the pinna and the posterior part of the external auditory meatus.

The pharyngeal branch, the principal motor nerve of the pharynx, arises from the upper part of the inferior ganglion of the pneumogastric. It consists principally of filaments from the accessory portion of the spinal accessory: it passes across the internal carotid artery (in front or behind) to the upper border of the Middle constrictor, where it divides into numerous filaments, which join with those from the glossopharyngeal, superior laryngeal (its external branch), and sympathetic, to form the pharyngeal plexus, from which branches are distributed to the muscles and mucous membrane of the pharynx and the muscles of the soft palate. From the pharyngeal plexus a minute filament (lingual branch) is given off, which descends and joins the hypoglossal nerve as it winds round the occipital artery.

The superior laryngeal is the nerve of sensation to the larynx. It is larger than the preceding, and arises from the middle of the inferior ganglion of the pneumogastric. It consists principally of filaments from the accessory portion of the spinal accessory. In its course it receives a branch from the superior cervical ganglion of the sympathetic. It descends by the side of the pharynx behind the internal carotid, where it divides into two branches, the external and internal laryngeal.

The external laryngeal branch, the smaller, descends by the side of the larynx, beneath the Sterno-thyroid, to supply the Crico-thyroid muscle. It gives branches to the pharyngeal plexus and the Inferior constrictor, and communicates with the superior cardiac nerve, behind the common carotid.

The internal laryngeal branch descends to the opening in the thyro-hyoid membrane, through which it passes with the superior laryngeal artery, and is distributed to the mucous membrane of the larynx. A small branch communicates with the recurrent laryngeal nerve. The branches to the mucous membrane are distributed, some in front to the epiglottis, the base of the tongue, and the epiglottis'idean glands; while others pass backward, in the aryteno-epiglottis'idean fold, to supply the mucous membrane surrounding the superior orifice of the larynx, as well as the membrane which lines the cavity of the larynx as low down as the vocal cord. The filament which joins with the recurrent laryngeal descends beneath the mucous membrane on the inner surface of the thyroid cartilage, where the two nerves become united.

The inferior or recurrent laryngeal, so called from its reflected course, is the motor nerve of the larynx. It arises on the right side, in front of the subclavian artery; winds from before backward round that vessel, and ascends obliquely to the side of the trachea, behind the common carotid and behind or in front of the inferior thyroid artery. On the left side it arises in front of the arch of the aorta, and winds from before backward round the aorta just beyond where the remains of the ductus arteriosus are connected with it, and then ascends to the side of the trachea. The nerves on both sides ascend in the groove between the trachea and esophagus, and, passing under the lower border of the Inferior constrictor muscle, enter the larynx behind the articulation of the inferior cornu of the thyroid cartilage with the cricoid, being distributed to all the muscles of the larynx, except the Crico-thyroid. It communicates with the Superior laryngeal nerve and sends twigs to the mucous membrane below the true cords. The recurrent laryngeal, as it winds round the subclavian artery and aorta, gives off several cardiac filaments, which unite with the cardiac branches from the pneum-
mogastric and sympathetic. As it ascends in the neck it gives off cæsophageal branches, more numerous on the left than on the right side, which supply the mucous membrane and muscular coat of the cæsophagus; tracheal branches to the mucous membrane and muscular fibres of the trachea: and some pharyngeal filaments to the Inferior constrictor of the pharynx.

The **cervical cardiac branches**, two or three in number, arise from the pneumogastric, at the upper and lower part of the neck.

The **superior branches** are small, and communicate with the cardiac branches of the sympathetic. They can be traced to the great or deep cardiac plexus.

The **inferior branches**, one on each side, arise at the lower part of the neck, just above the first rib. On the right side this branch passes in front or by the side of the arteria innominata, and communicates with one of the cardiac nerves proceeding to the great or deep cardiac plexus. On the left side it passes in front of the arch of the aorta and joins the superficial cardiac plexus.

The **thoracic cardiac branches**, on the right side, arise from the trunk of the pneumogastric as it lies by the side of the trachea, and from its recurrent laryngeal branch, but on the left side from the recurrent nerve only; passing inward, they terminate in the deep cardiac plexus.

The **anterior pulmonary branches**, two or three in number, and of small size, are distributed on the anterior aspect of the root of the lungs. They join with filaments from the sympathetic, and form the **anterior pulmonary plexus**.

The **posterior pulmonary branches**, more numerous and larger than the anterior, are distributed on the posterior aspect of the root of the lung, some filaments going to the pericardium; they are joined by filaments from the third and fourth (sometimes also first and second) thoracic ganglia of the sympathetic, and form the **posterior pulmonary plexus**. Branches from both plexuses accompany the ramification of the air-tubes through the substance of the lungs.

The **oesophageal branches** are given off from the pneumogastric both above and below the pulmonary branches. The lower are more numerous and larger than the upper. They form, together with branches from the opposite nerve, the **oesophageal plexus, or plexus gulae**, which also supplies the pericardium.

The **gastric branches** are the terminal filaments of the pneumogastric nerve. The nerve on the right side is distributed to the posterior surface of the stomach, and joins the left side of the coeliac plexus and the splenic plexus. The nerve on the left side is distributed over the anterior surface of the stomach, some filaments passing across the great cul-de-sac, and others along the lesser curvature. They unite with branches of the right nerve and with the sympathetic, some filaments passing through the lesser omentum to the hepatic plexus.

**Surgical Anatomy.**—The laryngeal nerves are of considerable importance in considering some of the morbid conditions of the larynx. When the peripheral terminations of the superior laryngeal nerve are irritated by some foreign body passing over them, reflex spasm of the glottis is the result. When the trunk of this same nerve is pressed upon by, for instance, a goitre or an aneurism of the upper part of the carotid, we have a peculiar dry, brassy cough. When the nerve is paralyzed, we have anesthesia of the mucous membrane of the larynx, so that foreign bodies can readily enter the cavity, and, in consequence of its supplying the crico-thyroid muscle, the vocal cords cannot be made tense, and the voice is deep and hoarse. Paralysis of the superior laryngeal nerves may be the result of bulbar paralysis, may be a sequel to diphtheria, when both nerves are usually involved, or it may, though less commonly, be caused by the pressure of tumors or aneurisms, when the paralysis is generally unilateral. Irritation of the inferior laryngeal nerves produces spasm of the muscles of the larynx. When both these recurrent nerves are paralyzed, the vocal cords are motionless, in the so-called "cadaveric position"—that is to say, in the position in which they are found in ordinary tranquil respiration—neither closed as in phonation, nor open as in deep inspiratory efforts. When one recurrent nerve is paralyzed, the cord of the same side is motionless, while the opposite one crosses the middle line to accommodate itself to the affected one; hence phonation is present, but the voice is altered and weak in timbre. The recurrent laryngeal nerves may be paralyzed in bulbar paralysis or after diphtheria, when it usually affects both sides; or they may be affected by the pressure of aneurisms of the aorta, innominate or subclavian arteries; by mediastinal tumors; by brachiocele; or by cancer of the upper part of the cæsophagus, when the paralysis is often unilateral.
Eleventh Pair (Figs. 491, 492).

The Eleventh or Spinal Accessory Nerve consists of two parts—one the accessory part to the vagus, and the other the spinal portion.

The accessory part is the smaller of the two. Its superficial origin is by four or five delicate filaments from the side of the medulla, below the roots of the vagus. Its deep origin may be traced to a nucleus of gray matter in the medulla, just dorsal to the lower third of the olive and dorso-lateral to the hypoglossal nucleus. It passes outward to the jugular foramen, where it joins with the spinal portion, and is connected with the upper ganglion of the vagus by one or two filaments. It then separates from the spinal portion, passes through the foramen, and is continued over but adherent to the surface of the inferior ganglion, or ganglion of the trunk of the vagus, to be distributed principally to the pharyngeal and superior laryngeal branches of the pneumogastric. Through the pharyngeal branch it probably supplies the muscles of the soft palate (see page 425). Some few filaments from it are continued into the trunk of the vagus below the ganglion, to be distributed with the recurrent laryngeal nerve and probably also with the cardiac nerves.

The spinal portion is firm in texture. Its superficial origin is by several filaments from the lateral tract of the cord, as low down as the sixth cervical nerve. Its deep origin may be traced to the intermedio-lateral tract (lateral horn) of the gray matter of the cord, where it forms a column of cells reaching, above, to the lower end of the nucleus of the accessory part of the nerve. This portion of the nerve ascends between the ligamentum denticulatum and the posterior roots of the spinal nerves, enters the skull through the foramen magnum, and is then directed outward to the jugular foramen, through which it passes, lying in the same sheath as the pneumogastric, but separated from it by a fold of the arachnoid. In the jugular foramen it joins with the accessory portion. At its exit from the jugular foramen it passes backward, either in front of or behind the internal jugular vein, and descends obliquely behind the Digastric and Stylo-hyoid muscles to the upper part of the Sterno-mastoid. It pierces that muscle, and passes obliquely across the occipital triangle, to terminate in the deep surface of the Trapezius. This nerve gives several branches to the Sterno-mastoid during its passage through it, and joins in its substance with branches from the second cervical, which supply the muscle. In the occipital triangle it joins with the second and third cervical nerves and assists in the formation of the cervical plexus. Beneath the Trapezius it joins with the third and fourth cervical nerves to form a sort of plexus, from which fibres are distributed to the muscle.

Surgical Anatomy.—In cases of spasmodic torticollis in which all palliative treatment has failed, division or excision of a portion of the spinal accessory nerve has been resorted to. This may be done either along the anterior or posterior border of the Sterno-mastoid muscle. The former operation is performed by making an incision from the apex of the mastoid process, three inches in length, along the anterior border of the Sterno-mastoid muscle. The anterior border of the muscle is defined and pulled backward, so as to stretch the nerve, which is then to be sought for beneath the Digastric muscle, about two inches below the apex of the mastoid process. The other operation consists in making an incision along the posterior border of the muscle, so that the centre of the incision corresponds to the middle of this border of the muscle. The superficial structures having been divided and the border of the muscle defined, the nerve is to be sought for as it emerges from the muscle to cross the occipital triangle. When found, it is to be traced upward through the muscle, and a portion of it excised above the point where it gives off its branches to the Sterno-mastoid. In this operation one of the descending branches of the superficial cervical plexus is liable to be mistaken for the nerve.

Twelfth Pair (Fig. 493).

The Twelfth or Hypoglossal Nerve is the motor nerve of the tongue. Its superficial origin is by several filaments, from ten to fifteen in number, from the groove between the pyramid and olivary body, in a continuous line with the anterior roots of the spinal nerves. Its deep origin can be traced to a nucleus of gray matter lying under the lower part of the fasciculus teres (trigonum hypo-
glossi) in the floor of the fourth ventricle, and extending downward into the closed portion of the medulla. The filaments of this nerve are collected into two bundles which perforate the dura mater separately, opposite the anterior condyloid foramen, and unite together after their passage through it. In those cases in which the anterior condyloid foramen in the occipital bone is double these two portions of the nerve are separated by the small piece of bone which divides the foramen. The nerve descends almost vertically to a point corresponding with the angle of the jaw. It is at first deeply seated beneath the internal carotid artery and internal jugular vein, and intimately connected with the pneumogastric nerve; it then passes forward between the vein and artery, and lower down in the neck becomes superficial below the Digastric muscle. The nerve then loops round the occipital artery, the sterno-mastoid branch of which hooks over the nerve, and crosses the external carotid and its lingual branch below the tendon of the Digastric muscle. It then passes beneath the tendon of the digastric, the stylo-hyoid, and the Mylohyoid muscles, lying on the Hyo-glossus, accompanied by the ranine vein, and communicates at the anterior border of the latter muscle with the lingual (gustatory) nerve; it is then continued forward in the fibres of the Genio-hyo-glossus muscle as far as the tip of the tongue, distributing branches to its substance.

The branches of communication are—with the

- Pneumogastric
- First and Second Cervical Nerves
- Sympathetic
- Lingual (gustatory)

The first mentioned takes place close to the exit of the nerve from the skull, numerous filaments passing between the hypoglossal and lower ganglion of the pneumogastric through the mass of connective tissue which here unites the two nerves. It also communicates with the pharyngeal plexus by a minute filament as it winds round the occipital artery (lingual branch, see page 821).

The communication with the sympathetic takes place opposite the atlas by branches derived from the superior cervical ganglion, and in the same situation the nerve is joined by filaments derived from the loop connecting the first two cervical nerves.

The communication with the lingual (gustatory) takes place near the anterior border of the Hyo-glossus muscle by numerous filaments which ascend upon it.

The branches of distribution are—the

- Meningeal
- Descendens hypoglossi
- Thyro-hyoid
- Muscular

**Meningeal Branches.**—As the hypoglossal nerve passes through the anterior
condyloid foramen it gives off, according to Luschka, several filaments (recurrent) to the dura mater in the posterior fossa of the base base of the skull.

The descendens hypoglossi is a long slender branch which quits the hypoglossal where it turns round the occipital artery. It descends obliquely across the sheath of the carotid vessels, and joins the communicating branches from the second and third cervical nerves, just below the middle of the neck, to form a loop. From the convexity of this loop branches pass forward to supply the Sterno-hyoid, Sterno-thyroid, and both bellies of the Omo-hyoid. According to Arnold, another filament descends in front of the vessels into the chest and joins the cardiac and phrenic nerves. The descendens hypoglossi is occasionally contained in the sheath of the carotid vessels, being sometimes placed over, and sometimes beneath, the internal jugular vein. The fibres of this nerve are chiefly derived from the first and second cervical nerves by means of the filaments of communication already mentioned.

The thyro-hyoid is a small branch arising from the hypoglossal near the posterior border of the Hyo-glossus; it passes obliquely across the great cornu of the hyoid bone and supplies the Thyro-hyoid muscle.

The muscular branches are distributed to the Stylo-glossus, Hyo-glossus, Genio-hyoid, and Genio-hyo-glossus muscles. At the under surface of the tongue numerous slender branches pass upward into the substance of the organ to supply its muscular structure.

Surgical Anatomy.—The hypoglossal nerve is an important guide in the operation of ligation of the lingual artery (see page 553).
THE SPINAL NERVES.

The spinal nerves are so called because they take their origin from the spinal cord, and are transmitted through the intervertebral foramina on either side of the spinal column. There are thirty-one pairs of spinal nerves, which are arranged into the following groups, corresponding to the region of the spine through which they pass:

- Cervical: 8 pairs.
- Dorsal: 12 pairs.
- Lumbar: 5 pairs.
- Sacral: 5 pairs.
- Coccygeal: 1 pair.

It will be observed that each group of nerves corresponds in number with the vertebrae in that region, except the cervical and coccygeal.

Each spinal nerve arises by two roots, an anterior or motor root, and a posterior or sensory root.

Roots of the Spinal Nerves.

The Anterior Roots.—The superficial origin is from a somewhat irregular series of depressions which map out a longitudinal area opposite the anterior cornu of gray matter on the antero-lateral column of the spinal cord, gradually approaching toward the anterior median fissure as they descend. To the deep origin the fibres can be traced through the antero-lateral column; the roots, after penetrating horizontally through the longitudinal fibres of this tract, enter the gray substance of the anterior cornu, where their fibrils diverge in several directions; some, passing inward, are continued across the anterior commissure in front of the central canal, to become continuous with the axis-cylinder processes of the large cells of the anterior cornu of the opposite side; others terminate in the mesial group of cells of the anterior column of the same side; other fibrils pass outward, some to become continuous with the axis-cylinder processes of the group of cells in the lateral part of the anterior column; and others enter the lateral column of the same side, where, turning upward, they pursue their course as longitudinal fibres. The remaining fibrils pass backward to the posterior horn, where they are continuous with the axis-cylinders of the cells at the base of the posterior cornu.

The Posterior Roots.—The superficial origin is from the postero-lateral fissure of the cord. The deep origin is from the gray substance of the posterior cornu, either directly through the substantia gelatinosa, or indirectly, by first passing through the white matter of the posterior column and winding round in front of the caput cornu. Those which enter the gray matter at once for the most part turn upward and downward, and become continuous with the fine nerve-plexus in the central portion of the gray matter; some few fibres pass transversely through the posterior commissure to the opposite side, and others into the anterior cornu of the same side. Those fibres which enter the gray matter in front of the caput cornu reach the posterior vesicular column (Clark's column) and blend with it, a few fibres passing through it, to become longitudinal in the posterior column of the cord.

The anterior roots are smaller than the posterior, devoid of ganglionic enlargement, and their component fibrils are collected into two bundles near the intervertebral foramina.

The posterior roots of the nerves are larger, but the individual filaments are finer and more delicate than those of the anterior. As their component fibrils pass outward, toward the aperture in the dura mater, they coalesce into two bundles, receive a tubular sheath from that membrane, and enter the ganglion which is developed upon each root.

The posterior root of the first cervical nerve forms an exception to these characters. It is smaller than the anterior, has frequently no ganglion developed upon it, and when the ganglion exists it is often situated within the dura mater.
Ganglia of the Spinal Nerves.

A ganglion is developed upon the posterior root of each of the spinal nerves. These ganglia are of an oval form and of a reddish color; they bear a proportion in size to the nerves upon which they are formed, and are placed in the intervertebral foramina, external to the point where the nerves perforate the dura mater. Each ganglion is bifid internally, where it is joined by the two bundles of the posterior root, the two portions being united into a single mass externally. The ganglion upon the first and second cervical nerves forms an exception to these characters, being placed on the arches of the vertebrae over which the nerves pass. The ganglia, also, of the sacral nerves are placed within the spinal canal; and that on the coccygeal nerve, also in the canal, about the middle of its posterior root.

Distribution of the Spinal Nerves.

Immediately beyond the ganglion the two roots coalesce, their fibres intermingle, and the trunk thus formed passes out of the intervertebral foramen, and divides into a posterior division for the supply of the posterior part of the body, and an anterior division for the supply of the anterior part of the body, each containing fibres from both roots. Before division each trunk gives off a recurrent branch to the dura mater of the cord.

The posterior divisions of the spinal nerves are generally smaller than the anterior; they arise from the trunk resulting from the union of the roots in the intravertebral foramina, and, passing backward, divide into internal and external branches, which are distributed to the muscles and integument behind the spine. The first cervical, the fourth and fifth sacral, and the coccygeal nerves are exceptions to these characters.

The anterior divisions of the spinal nerves supply the parts of the body in front of the spine, including the limbs. They are for the most part larger than the posterior divisions. Each division is connected with the sympathetic by slender filaments from which a communicating branch runs to the recurrent filament from the trunk. In the dorsal region the anterior divisions of the spinal nerves are completely separate from each other, and are uniform in their distribution; but in the cervical, lumbar, and sacral regions they form intricate plexuses previous to their distribution.

Points of Emergence of the Spinal Nerves.

The roots of the spinal nerves from their origin in the cord run obliquely downward to their point of exit from the intervertebral foramina, the amount of obliquity varying in different regions of the spine, and being greater in the lower than the upper part. The level of their emergence from the cord is within certain

</table>
limits variable, and of course does not correspond to the point of emergence of the nerve from the intervertebral foramina. The preceding table, from Macalister, shows as accurately as can be shown the relation of these points of origin from the spinal cord to the bodies and spinous processes of the vertebrae.

THE CERVICAL NERVES.

The roots of the cervical nerves increase in size from the first to the fifth, and then remain the same size to the eighth. The posterior roots bear a proportion to the anterior as 3 to 1, which is much greater than in any other region, the individual filaments being also much larger than those of the anterior roots. In direction the roots of the cervical are less oblique than those of the other spinal nerves. The first cervical nerve is directed a little upward and outward; the second is horizontal; the others are directed obliquely downward and outward, the lowest being the most oblique, and consequently longer than the upper, the distance between their place of origin and their point of exit from the spinal canal never exceeding the depth of one vertebra.

The trunk of the first cervical nerve (suboccipital) leaves the spinal canal between the occipital bone and the posterior arch of the atlas; the second, between the posterior arch of the atlas and the lamina of the axis; and the eighth (the last), between the last cervical and first dorsal vertebra.

Each nerve, at its exit from the intervertebral foramen, divides into a posterior and an anterior division. The anterior divisions of the four upper cervical nerves form the cervical plexus. The anterior divisions of the four lower cervical nerves, together with the first dorsal, form the brachial plexus.

Posterior Divisions of the Cervical Nerves (Fig. 495).

The posterior division of the first cervical (suboccipital) nerve differs from the posterior divisions of the other cervical nerves in not dividing into an internal and external branch. It is larger than the anterior division, and escapes from the spinal canal between the occipital bone and the posterior arch of the atlas, lying behind the vertebral artery. It enters the suboccipital triangle formed by the Rectus capitis posticus major, the Obliquus superior, and Obliquus inferior, and supplies the Recti and Obliqui muscles, and the Complexus. From the branch which supplies the Inferior oblique a filament is given off which joins the second cervical nerve. This nerve also occasionally gives off a cutaneous filament, which accompanies the occipital artery and communicates with the occipitalis major and minor nerves.

The posterior division of the second cervical nerve is three or four times greater than the anterior division, and the largest of all the posterior cervical divisions. It emerges from the spinal canal between the posterior arch of the atlas and lamina of the axis, below the Inferior oblique. It supplies this muscle, and receives a communicating filament from the first cervical. It then divides into an internal and external branch.

The internal branch, called, from its size and distribution, the occipitalis major, ascends obliquely inward between the Obliquus inferior and Complexus, and pierces the latter muscle and the Trapezius near their attachments to the cranium. It is now joined by a filament (third occipital) from the posterior division of the third cervical nerve, and, ascending on the back part of the head with the occipital artery, divides into two branches, which supply the integument of the scalp as far forward as the vertex, communicating with the occipitalis minor. It gives off an auricular branch to the back part of the ear and muscular branches to the Complexus. The external branch is often joined by the external branch of the posterior division of the third, and supplies the Splenius, Tracheo-mastoid, and Complexus.

The posterior division of the third cervical is smaller than the preceding, but larger than the fourth; it differs from the posterior divisions of the remaining cervical nerves in its supplying an additional filament, the third occipital nerve,
to the integument of the occiput. The posterior division of the third nerve, like the others, divides into an internal and external branch. The internal branch passes between the Complexus and Semispinalis, and, piercing the Splenius and Trapezius, supplies the skin over the latter muscle; the external branch joins with that of the posterior division of the second to supply the Splenius, Trachelo-masto-roid, and Complexus.

The third occipital nerve arises from the internal or cutaneous branch beneath the Trapezius; it then pierces that muscle, and supplies the skin on the lower and back part of the head. It lies to the inner side of the occipitalis major, with which it is connected.

The posterior division of the suboccipital nerve and the internal branches of the posterior divisions of the second and third cervical nerves are occasionally joined beneath the Complexus by communicating branches. This communication is described by Cruveilhier as the posterior cervical plexus.

The posterior divisions of the fourth, fifth, sixth, seventh, and eighth cervical nerves (Fig. 502) pass backward, and divide, behind the Posterior intertransverse
muscles, into internal and external branches. The internal branches, the larger, are distributed differently in the upper and lower part of the neck. Those derived from the fourth and fifth nerves pass between the Complexus and Semispinalis muscles, and, having reached the spinous processes, perforate the aponeurosis of the Splenius and Trapezius, and are continued outward to the integument over the Trapezius, whilst those derived from the three lowest cervical nerves are the smallest, and are placed beneath the Semispinalis colli, which they supply, and then pass into the Interspinales, Multifidus spine, and Complexus, and send twigs through this latter muscle to supply the integument near the spinous processes (Hirschfeld). The external branches supply the muscles at the side of the neck—viz. the Cervicalis ascendens, Transversalis colli, and Trachelomastoid.

Anterior Divisions of the Cervical Nerves.

The anterior division of the first or suboccipital nerve is of small size. It escapes from the spinal canal through a groove upon the posterior arch of the atlas. In this groove it lies beneath the vertebral artery, to the inner side of the Rectus capitis lateralis. As it crosses the foramen in the transverse process of the atlas it receives a filament from the sympathetic on the vertebral artery. It then descends, in front of this process, to join with the ascending branch from the second cervical nerve.

Communicating filaments from the loop between this nerve and the second join the pneumogastric, the hypoglossal, and sympathetic (superior cervical ganglion), and some branches are distributed to the Rectus lateralis and the two Anterior recti. The fibres communicating with the hypoglossal are mostly continued into its descendens hypoglossei branch (see page 825).

The anterior division of the second cervical nerve escapes from the spinal canal, between the posterior arch of the atlas and the lamina of the axis, and, passing forward on the outer side of the vertebral artery, divides in front of the Intervertebral muscle into an ascending branch, which joins the first cervical, and descending branches, which join branches from the third. These last-named intercommunicating branches of the second and third cervical nerves, give off the small occipital, the great auricular, and the superficial cervical nerves. The nerve also gives off one of the communicantes hypoglossi, and a filament to the Sterno-mastoid which communicates in the substance of the muscle with the spinal accessory.

The anterior division of the third cervical nerve is double the size of the preceding. At its exit from the intervertebral foramen it passes downward and outward beneath the Sterno-mastoid, and divides into branches. The ascending ones join with branches of the second cervical, and this combination gives off, as already stated, the small occipital, the great auricular, and the superficial cervical nerves. The descending branches pass down in front of the Scalenus anticus, and are as follows: One of the communicantes hypoglossi; a branch to the supraclavicular nerves; a filament to assist in forming the phrenic; and muscular branches to the Levator anguli scapulae and Trapezius; this latter nerve communicates beneath the muscle with the spinal accessory. Sometimes the nerve to the Scalenus medius is derived from this source.

The anterior division of the fourth cervical is of the same size as the preceding. It sends a communicating branch to the fifth cervical, and, passing downward and outward, unites with a branch from the third, and from this union are derived numerous filaments which cross the posterior triangle of the neck, forming the supraclavicular nerves. It also gives a branch to the phrenic nerve whilst it is contained in the intertransverse space, and sometimes a branch to the Scalenus medius muscle. It also gives a branch to the Levator anguli scapulae and to the

1 According to Valentin, the anterior division of the suboccipital also distributes filaments to the occipito-atlantal articulation and mastoid process of the temporal bone.
Trapezius, which unites with the branch given off from the third nerve, and
communicates beneath the muscle with the spinal accessory.

The anterior divisions of the fifth, sixth, seventh, and eighth cervical nerves
are remarkable for their large size. They are much larger than the preceding
nerves, and are all of equal size. They assist in the formation of the brachial
plexus.

The Cervical Plexus.

The cervical plexus (Fig. 496) is formed, as above described, by the anterior
divisions of the four upper cervical nerves. It is situated opposite the four upper
cervical vertebrae, resting upon the Levator anguli scapulae and Scalenus medius
muscles, and covered in by the Sterno-mastoid.

Its branches may be divided into two groups, superficial and deep, which may
be thus arranged:

Superficial

| Ascending      | Occipitalis minor. |
|               | Auricularis magnus. |
|               | Superficialis colli. |
| Descending    | Supraclavicular     |
|               | Suprasternal.        |
|               | Supraclavicular.     |
|               | Supra-acromial.      |
| Internal      | Communicating.       |
|               | Muscular.            |
|               | Communicans hypoglossi. |
|               | Phrenic.             |
| External      | Communicating.       |
|               | Muscular.            |

Superficial Branches of the Cervical Plexus.

The Occipitalis minor (Fig. 502) arises from the second and third cervical
nerves; it curves round the posterior border of the Sterno-mastoid, and ascend,
running parallel to the posterior border of the muscle, to the back part of the
side of the head. Near the cranium it perforates the deep fascia, and is continued
upward along the side of the head behind the ear, supplying the integument, and
communicating with the occipitalis major, the auricularis magnus, and with the
posterior auricular branch of the facial.

This nerve gives off an auricular branch, which supplies the integument of
the upper and back part of the auricle, communicating with the mastoid branch
of the auricularis magnus. This branch is occasionally derived from the great
occipital nerve. The occipitalis minor varies in size; it is occasionally double.

The Auricularis Magnus is the largest of the ascending branches. It arises
from the second and third cervical nerves, winds round the posterior border of
the Sterno-mastoid, and, after perforating the deep fascia, ascend upon that
muscle beneath the Platysma to the parotid gland, where it divides into facial,
auricular, and mastoid branches.

The facial branches pass across the parotid, and are distributed to the integu-
ment of the face over the parotid gland; others penetrate the substance of the
gland and communicate with the facial nerve.

The auricular branches ascend to supply the integument of the back part of
the pinna, except at its upper part, communicating with the auricular branches
of the facial and pneumogastric nerves.

The mastoid branch communicates with the occipitalis minor and the posterior
auricular branch of the facial, and is distributed to the integument behind the ear.

The Superficialis Colli arises from the second and third cervical nerves, turns
round the posterior border of the Sterno-mastoid about its middle, and, passing
obliquely forward beneath the external jugular vein to the anterior border of that
muscle, perforates the deep cervical fascia, and divides beneath the Platysma into two branches which are distributed to the antero-lateral parts of the neck.

The ascending branch gives a filament which accompanies the external jugular vein; it then passes upward to the submaxillary region, and divides into branches, some of which form a plexus with the cervical branches of the facial nerve beneath the Platysma; others pierce that muscle, supply it, and are distributed to the integument of the upper half of the neck, at its fore part, as high as the chin.

The descending branch (occasionally represented by two or more filaments) pierces the Platysma, and is distributed to the integument of the side and front of the neck, as low as the sternum.

The Descending or supra-clavicular branches arise from the third and fourth cervical nerves: emerging with the posterior border of the Sterno-mastoid, they descend in the interval between that muscle and the Trapezius, and divide into branches, which are arranged, according to their position, into three groups.

The inner or suprasternal branches cross obliquely over the clavicular and sternal attachments of the Sterno-mastoid, and supply the integument as far as the median line.

The middle or supraclavicular branches cross the clavicle, and supply the integument over the Pectoral and Deltoid muscles, communicating with the cutaneous branches of the upper intercostal nerves.

The external or supra-acromial branches pass obliquely across the outer surface of the Trapezius and the acromion, and supply the integument of the upper and back part of the shoulder.

The communicating branches consist of several filaments which pass from the loop between the first and second cervical nerves in front of the atlas to the pneumogastric, hypoglossal (see page 825 and Fig. 493) and sympathetic, and a communicating branch between the fourth and fifth cervical.

Muscular branches supply the Anterior recti and the Rectus lateralis muscles; they proceed from the first cervical nerve and from the loop formed between it and the second. The Longus colli is supplied from the third and the fourth.

The Communicans Hypoglossi (Fig. 493) consists usually of two filaments, one being derived from the second, and the other from the third cervical. These filaments pass downward on the outer side of the internal jugular vein, cross in front of the vein a little below the middle of the neck, and form a loop with the descendens hypoglossi in front of the sheath of the carotid vessels (see page 825). Occasionally, the junction of these nerves takes place within the sheath.

The Phrenic Nerve (internal respiratory of Bell) arises chiefly from the fourth cervical nerve, with a few filaments from the third and a communicating branch from the fifth. It descends to the root of the neck, running obliquely across the front of the Scalenus anticus, passes over the first part of the subclavian artery, between it and the subclavian vein, and, as it enters the chest, crosses the internal mammary artery near its origin. Within the chest it descends nearly vertically in front of the root of the lung and by the side of the pericardium, between it and the mediastinal portion of the pleura, to the Diaphragm, where it divides into branches, which separately pierce that muscle and are distributed to its under surface.

The two phrenic nerves differ in their length, and also in their relations at the upper part of the thorax.

The right nerve is situated more deeply, and is shorter and more vertical in direction than the left; it lies on the outer side of the right vena innominata and superior vena cava.

The left nerve is rather longer than the right, from the inclination of the heart to the left side, and from the Diaphragm being lower on this than on the opposite side. At the upper part of the thorax it crosses in front of the arch of the aorta to the root of the lung.

Each nerve supplies filaments to the pericardium and pleura, and near the chest is joined by a filament from the sympathetic, and occasionally by one from the union of the descendens hypoglossi with the spinal nerves; this filament is found, according to Swan, only on the left side. It is also usually connected by a filament with the nerve to the Subclavius muscle. Branches have been described as passing to the peritoneum.

From the right nerve one or two filaments pass to join in a small ganglion with phrenic branches of the solar plexus; and branches from this ganglion are distributed to the hepatic plexus, the suprarenal capsule, and inferior vena cava. From the left nerve filaments pass to join the phrenic plexus of the sympathetic, but without any ganglionic enlargement.

Communicating Branches.—The deep branches of the external series of the cervical plexus communicate with the spinal accessory nerve, in the substance of the Sterno-mastoid muscle, in the occipital triangle, and beneath the Trapezius.

Muscular branches are distributed to the Sterno-mastoid, Trapezius, Levator anguli scapulae, and Scalenus medius.

The branch for the Sterno-mastoid is derived from the second cervical; the Trapezius and Levator anguli scapulae receive branches from the third and fourth. The Scalenus medius is supplied sometimes from the third, sometimes the fourth, and occasionally from both nerves.
The Brachial Plexus (Fig. 497).

The Brachial Plexus is formed by the union of the anterior branches of the four lower cervical and the greater part of the first dorsal nerves, receiving also a fasciculus from the fourth cervical nerve. It extends from the lower part of the side of the neck to the axilla. It is very broad, and presents little of a plexiform arrangement at its commencement. It is narrow opposite the clavicle, becomes broad and forms a more dense interlacement in the axilla, and divides opposite the coracoid process into numerous branches for the supply of the upper limb. The nerves which form the plexus are all similar in size, and their mode of communication is subject to considerable variation, so that no one plan can be given as applying to every case. The following appears, however, to be the most constant arrangement: the fifth and sixth cervical unite together soon after their exit from the intervertebral foramina to form a common trunk. The eighth cervical and first dorsal also unite to form one trunk. So that the nerves forming the plexus, as they lie on the Scalenus medius external to the outer border of the

Fig. 497.—Plan of the brachial plexus.

Scalenus anticus, are blended into three trunks—an upper one, formed by the junction of the fifth and sixth cervical nerves; a middle one, consisting of the seventh cervical nerve; and a lower one, formed by the junction of the eighth cervical and first dorsal nerves. As they pass beneath the clavicle, each of these three trunks divides into two branches, an anterior and a posterior. The anterior divisions of the upper and middle trunks then unite to form a common cord, which is situated on the outer side of the middle part of the axillary artery, and is called the outer cord of the brachial plexus. The anterior division of the
lower trunk, formed by the union of the eighth cervical and first dorsal, passes down on the inner side of the axillary artery in the middle of the axilla, and forms the inner cord of the brachial plexus. The posterior divisions of the upper

trunk (formed by the junction of the fifth and sixth nerves) and of the middle trunk (the seventh nerve) unite together to form the posterior cord of the brachial plexus, which is situated behind the second portion of the axillary artery. From this posterior cord are given off the two lower subscapular nerves, the upper subscapular nerve being given off from the posterior division of the outer trunk prior to its junction with the posterior division of the middle trunk. The posterior cord divides into the circumflex and musculo-spiral nerves. The musculo-

Deep branch.

Fig. 500.—Nerves of the left upper extremity.

Spiral nerve is subsequently joined by the posterior division of the inner trunk, formed by the union of the eighth cervical and first dorsal.
The brachial plexus communicates with the cervical plexus by a branch from the fourth to the fifth nerve, and with the phrenic nerve by a branch from the fifth cervical, which joins that nerve on the Anterior scalenus muscle: the cervical and first dorsal nerves are also joined by filaments from the middle and inferior cervical ganglia of the sympathetic, close to their exit from the intervertebral foramina.

**Relations.—** In the neck the brachial plexus lies at the first between the Anterior and Middle scaleni muscles, and then above and to the outer side of the subclavian artery: it then passes behind the clavicle and Subclavius muscle, lying upon the first serration of the Serratus magnus, and the Subscapularis muscles. In the axilla it is placed on the outer side of the first portion of the axillary artery; it surrounds the artery in the second part of its course, one cord lying upon the outer side of that vessel, one on the inner side, and one behind it, and at the lower part of the axillary space gives off its terminal branches to the upper extremity.

**Branches.—** The branches of the brachial plexus are arranged in two groups—viz. those given off above the clavicle, and those below that bone.

**Branches above the Clavicle.**

</tbody>
</table>

The communicating branch with the phrenic is derived from the fifth cervical nerve or from the loop between the fifth and sixth; it joins the phrenic on the Anterior scalenus muscle.

The muscular branches supply the Longus colli, Scaleni, Rhomboidei, and Subclavius muscles. Those for the Longus colli and Scaleni arise from the lower cervical nerves at their exit from the intervertebral foramina. The Rhomboid branch arises from the fifth cervical, pierces the Scalenum medius, and passes beneath the Levator anguli scapulae, which it occasionally supplies, to the Rhomboid muscles. The nerve to the Subclavius is a small filament which arises from the fifth cervical at its point of junction with the sixth nerve; it descends in front of the subclavian artery to the Subclavius muscle, and is usually connected by a filament with the phrenic nerve.

The posterior thoracic nerve (long thoracic, external respiratory of Bell) (Fig. 500) supplies the Serratus magnus, and is remarkable for the length of its course. It sometimes arises by two roots from the fifth and sixth cervical nerves immediately after their exit from the intervertebral foramina, but generally by three roots from the fifth, sixth, and seventh nerves. These unite in the substance of the Middle scalenus muscle, and, after emerging from it, the nerve passes down behind the brachial plexus and the axillary vessels, resting on the outer surface of the Serratus magnus. It extends along the side of the chest to the lower border of that muscle, supplying filaments to each of its digitations.

The suprascapular nerve (Fig. 501) arises from the cord formed by the fifth and sixth cervical nerves; passing obliquely outward beneath the Trapezius, it enters the supraspinous fossa, through the notch in the upper border of the scapula; and, passing beneath the Supraspinatus muscle, curves in front of the spine of the scapula to the infraspinous fossa. In the supraspinous fossa it gives off two branches to the Supraspinatus muscle, and an articual filament to the shoulder-joint; and in the infraspinous fossa it gives off two branches to the Infraspinatus muscle, besides some filaments to the shoulder-joint and scapula.

**Branches below the Clavicle.**

The branches below the clavicle are derived from the three cords, as follows:

*From the outer cord arise the external of the two anterior thoracic nerves, the musculo-cutaneous nerve, the nerve to the Coraco-brachialis muscle, and the outer head of the median.*
From the inner cord arise the internal of the two anterior thoracic nerves, the internal cutaneous, the lesser internal cutaneous (nerve of Wrisberg), the ulnar, and inner head of the median.

From the posterior cord arise two of the three subscapular nerves, the third arising from the posterior division of the trunk formed by the fifth and sixth cervical nerves; the cord then divides into the musculo-spiral and circumflex nerves.

These may be arranged according to the parts they supply:

| To the chest | . . . Anterior thoracic. |
| To the shoulder | . . . Subscapular. |
| . . . Circumflex. |
| . . . Musculo-cutaneous. |
| . . . Internal cutaneous. |
| . . . Lesser internal cutaneous. |
| To the arm, forearm, and hand | . . . Median. |
| . . . Ulnar. |
| . . . Musculo-spiral. |

The fasciculi of which these nerves are composed may be traced through the plexus to the spinal nerves from which they originate. They are as follows:

- External anterior thoracic from 5th, 6th, and 7th cervical.
- Internal anterior thoracic " 8th cervical and 1st dorsal.
- Subscapular " 5th, 6th, 7th, and 8th cervical.
- Circumflex " 5th, 6th, 7th, and 8th cervical.
- Musculo-cutaneous " 5th, 6th, and 7th cervical.
- Internal cutaneous " 8th cervical and 1st dorsal.
- Lesser internal cutaneous " 1st dorsal.
- Median " 6th, 7th, and 8th cervical, and 1st dorsal.
- Ulnar " 8th cervical and 1st dorsal.
- Musculo-spiral " 6th, 7th, and 8th cervical, and 1st dorsal.

The Anterior Thoracic Nerves (Fig. 500), two in number, supply the Pectoral muscles.

The external or superficial nerve, the larger of the two, arises from the outer cord of the brachial plexus, through which its fibres may be traced to the fifth, sixth, and seventh cervical nerves. It passes inward, across the axillary artery and vein, pierces the costo-coracoid membrane, and is distributed to the under surface of the Pectoralis major. It sends down a communicating filament to join the internal nerve, which forms a loop round the inner side of the axillary artery.

The internal or deep nerve arises from the inner cord, and through it from the eighth cervical and first dorsal. It passes upward between the axillary artery and vein, and joins with the filament from the superficial nerve. It then passes to the under surface of the Pectoralis minor muscle, where it divides into a number of branches, which supply the muscle on its under surface. Some of the branches pass through the muscle; others wind round its upper border and pierce the costo-coracoid membrane to supply the Pectoralis major.

The Subscapular Nerves, three in number, supply the Subscapularis, Teres major, and Latissimus dorsi muscles. The fasciculi of which they are composed may be traced to the fifth, sixth, seventh, and eighth cervical nerves.

The upper subscapular nerve, the smallest, enters the upper part of the Subscapularis muscle.

The lower subscapular nerve enters the axillary border of the Subscapularis and terminates in the Teres major. The latter muscle is sometimes supplied by a separate branch.

The middle or long subscapular, the largest of the three, follows the course of
THE BRACHIAL PLEXUS.

839

the subscapular artery, along the posterior wall of the axilla to the Latissimus dorsi, through which it may be traced as far as its lower border.

The Circumflex Nerve (Fig. 501) supplies some of the muscles and the integument of the shoulder and the shoulder-joint. It arises from the posterior cord of the brachial plexus, in common with the musculo-spiral nerve, and its fibres may be traced through the posterior cord to the fifth, sixth, seventh, and eighth cervical nerves. It is at first placed behind the axillary artery, between it and the Subscapularis muscle, and passes downward and outward to the lower border of that muscle. It then winds backward in company with the posterior circumflex artery, through a quadrilateral space bounded above by the Teres minor, below by the Teres major, internally by the long head of the Triceps, and externally by the neck of the humerus, and divides into two branches.

The upper branch winds round the surgical neck of the humerus, beneath the Deltoid, with the posterior circumflex vessels, as far as the anterior border of that muscle, supplying it, and giving off cutaneous branches, which pierce the muscle and ramify in the integument covering its lower part.

The lower branch, at its origin, distributes filaments to the Teres minor and back part of the Deltoid muscles. Upon the filament to the former muscle a gangliform enlargement usually exists. The nerve then pierces the deep fascia, and supplies the integument over the lower two-thirds of the posterior surface of the Deltoid, as well as that covering the long head of the Triceps.

The circumflex nerve, before its division, gives off an articular filament, which enters the shoulder-joint below the Subscapularis.

The Musculo-cutaneous Nerve (Fig. 500) (external cutaneous or perforans Cas-
serii) supplies some of the muscles of the arm and the integument of the fore-arm. It arises from the outer cord of the brachial plexus, opposite the lower border of the Pectoralis minor, receiving filaments from the fifth, sixth, and seventh cervical nerves. It perforates the Coraco-brachialis muscle, passes obliquely between the Biceps and Brachialis anticus to the outer side of the arm, and, a little above the elbow, winds round the outer border of the tendon of the Biceps, and, perforating the deep fascia, becomes cutaneous. This nerve in its course through the arm supplies the Coraco-brachialis (this branch often arises separately from the outer cord), Biceps, and part of the Brachialis anticus muscles. It sends a small branch to the bone, which enters the nutrient foramen with the accompanying artery and a filament, from the branch supplying the Brachialis anticus, to the elbow-joint.

The cutaneous portion of the nerve passes behind the median cephalic vein, and divides, opposite the elbow-joint, into an anterior and a posterior branch.

The anterior branch descends along the radial border of the forearm to the wrist, and supplies the integument over the outer half of the anterior surface. At the wrist-joint it is placed in front of the radial artery, and some filaments, piercing the deep fascia, accompany that vessel to the back of the wrist, supplying the carpus. The nerve then passes downward to the ball of the thumb, where it terminates in cutaneous filaments. It communicates with a branch from the radial nerve and the palmar cutaneous branch of the median.

The posterior branch passes downward along the back part of the radial side of the forearm to the wrist. It supplies the integument of the lower third of the forearm, communicating with the radial nerve and the lower external cutaneous branch of the musculo-spiral.

The Internal Cutaneous Nerve (Fig. 500) is one of the smallest branches of the brachial plexus. It arises from the inner cord in common with the ulnar and internal head of the median, and at its commencement is placed on the inner side of the axillary artery. It derives its fibres from the eighth cervical and first dorsal nerves. It passes down the inner side of the arm, pierces the deep fascia with the basilic vein, about the middle of the limb, and, becoming cutaneous, divides into two branches, anterior and posterior.

This nerve gives off, near the axilla, a cutaneous filament, which pierces the
fascia and supplies the integument covering the Biceps muscle nearly as far as the elbow. This filament lies a little external to the common trunk, from which it arises.

The anterior branch, the larger of the two, passes usually in front of, but occasionally behind, the median basilic vein. It then descends on the anterior surface of the ulnar side of the forearm, distributing filaments to the integument as far as the wrist, and communicating with a cutaneous branch of the ulnar nerve.

The posterior branch passes obliquely downward on the inner side of the basilic vein, passes in front of, or over, the internal condyle of the humerus to the back of the forearm, and descends on the posterior surface of its ulnar side as far as the wrist, distributing filaments to the integument. It communicates, above the elbow, with the lesser internal cutaneous, and above the wrist with the dorsal cutaneous branch of the ulnar nerve (Swan).

The Lesser Internal Cutaneous Nerve (nerve of Wrisberg) (Fig. 500) is distributed to the integument on the inner side of the arm. It is the smallest of the branches of the brachial plexus, and, arising from the inner cord with the internal cutaneous and ulnar nerves, receives its fibres from the first dorsal nerve. It passes through the axillary space, at first lying behind, and then on the inner side of the axillary vein, and communicates with the intercosto-humeral nerve. It descends along the inner side of the brachial artery to the middle of the arm, where it pierces the deep fascia, and is distributed to the integument of the back part of the lower third of the arm, extending as far as the elbow, where some filaments are lost in the integument in front of the inner condyle, and others over the olecranon. It communicates with the posterior branch of the internal cutaneous nerve.

In some cases the nerve of Wrisberg and intercosto-humeral are connected by two or three filaments which form a plexus at the back part of the axilla. In other cases the intercosto-humeral is of large size, and takes the place of the nerve of Wrisberg, receiving merely a filament of communication from the brachial plexus, which represents the latter nerve. In other cases this filament is wanting, the place of the nerve of Wrisberg being supplied entirely from the intercosto-humeral.

The Median Nerve (Fig. 500) has received its name from the course it takes along the middle of the arm and forearm to the hand, lying between the ulnar and the musculo-spiral and radial nerves. It arises by two roots, one from the outer, and one from the inner, cord of the brachial plexus; these embrace the lower part of the axillary artery, uniting either in front or on the outer side of that vessel. It receives filaments from the sixth, seventh, and eighth cervical and the first dorsal. As it descends through the arm, it lies at first on the outer side of the brachial artery, crosses that vessel in the middle of its course, usually in front, but occasionally behind it, and lies on its inner side to the bend of the elbow, where it is placed beneath the bicipital fascia, and is separated from the elbow-joint by the Brachialis anticus. In the forearm it passes between the two heads of the Pronator radii teres, and descends beneath the Flexor sublimis, lying on the Flexor profundus, to within two inches above the annular ligament, where it becomes more superficial, lying between the tendons of the Flexor sublimis and Flexor carpi radialis, beneath, or rather to the ulnar side of, the tendon of the Palmaris longus, covered by the integument and fascia. It then passes beneath the annular ligament into the hand. In its course through the forearm it is accompanied by a small artery.

Branches.—No branches are given off from the median nerve in the arm. In the forearm its branches are muscular, anterior interosseous, and palmar cutaneous, and, according to Rudinger and Macalister, two articular twigs to the elbow-joint.

The muscular branches supply all the superficial muscles on the front of the forearm, except the Flexor carpi ulnaris. These branches are derived from the
nerve near the elbow. The radial head and index finger belly of the Flexor sublimis, each has a separate filament.

The anterior interosseous supplies the deep muscles on the front of the forearm, except the inner half of the Flexor profundus digitorum. It accompanies the anterior interosseous artery along the interosseous membrane, in the interval between the Flexor longus pollicis and Flexor profundus digitorum muscles, both of which it supplies, and terminates below in the Pronator quadratus.

The palmar cutaneous branch arises from the median nerve at the lower part of the forearm. It pierces the fascia above the annular ligament, and, descending over that ligament, divides into two branches; of which the outer supplies the skin over the ball of the thumb, and communicates with the anterior cutaneous branch of the musculo-cutaneous nerve; and the inner supplies the integument of the palm of the hand, communicating with the cutaneous branch of the ulnar.

In the palm of the hand the median nerve is covered by the integument and palmar fascia and crossed by the superficial palmar arch. It rests upon the tendons of the flexor muscles. In this situation it becomes enlarged, somewhat flattened, of a reddish color, and divides into two branches. Of these, the external supplies a muscular branch to some of the muscles of the thumb and digital branches to the thumb and index finger; the internal supplies digital branches to the contiguous sides of the index and middle and of the middle and ring fingers.

The branch to the muscles of the thumb is a short nerve which subdivides to supply the Abductor, Opponens, and outer head of the Flexor brevis pollicis muscles, the remaining muscles of this group being supplied by the ulnar nerve.

The digital branches are five in number. The first and second pass along the borders of the thumb, the external branch communicating with branches of the radial nerve. The third passes along the radial side of the index finger, and supplies the First lumbricalis muscle. The fourth subdivides to supply the adjacent sides of the index and middle fingers, and sends a branch to the Second lumbricalis muscle. The fifth supplies the adjacent sides of the middle and ring fingers, and communicates with a branch from the ulnar nerve.

Each digital nerve, opposite the base of the first phalanx, gives off a dorsal branch, which joins the dorsal digital nerve from the radial and runs along the side of the dorsum of the finger, to end in the integument over the last phalanx. At the end of the finger the digital nerve divides into a palmar and a dorsal branch, the former of which supplies the extremity of the finger, and the latter ramifies round and beneath the nail. The digital nerves, as they run along the fingers, are placed superficial to the digital arteries.

The Ulnar Nerve (Fig. 500) is placed along the inner or ulnar side of the upper limb, and is distributed to the muscles and integument of the forearm and hand. It is smaller than the median, behind which it is placed, diverging from it in its course down the arm. It arises from the inner cord of the brachial plexus, in common with the inner head of the median and the internal cutaneous nerve, and derives its fibres from the eighth cervical and first dorsal nerves. At its commencement it lies at the inner side of the axillary artery, and holds the same relation with the brachial artery to the middle of the arm. From this point it runs obliquely across the internal head of the Triceps, pierces the internal intermuscular septum, and descends to the groove between the internal condyle and olecranon, accompanied by the inferior profunda artery. At the elbow it rests upon the back of the inner condyle, and passes into the forearm between the two heads of the Flexor carpi ulnaris. In the forearm it descends in a perfectly straight course along its ulnar side, lying upon the Flexor profundus digitorum, its upper half being covered by the Flexor carpi ulnaris, its lower half lying on the outer side of the muscle, covered by the integument and fascia. The ulnar artery, in the upper third of its course, is separated from the ulnar nerve by a considerable interval, but in the rest of its extent the nerve lies to its inner side. At the wrist the ulnar nerve
crosses the annular ligament on the outer side of the pisiform bone, to the inner side and a little behind the ulnar artery, and immediately beyond this bone divides into two branches, superficial and deep palmar.

The branches of the ulnar nerve are—

- **Articular (elbow).**
- **Muscular.**
- **Cutaneous.**
- **Dorsal cutaneous.**
- **Articular (wrist).**

The **articular branches** distributed to the elbow-joint consist of several small filaments. They arise from the nerve as it lies in the groove between the inner condyle and olecranon.

The **muscular branches** are two in number—one supplying the Flexor carpi ulnaris; the other, the inner half of the Flexor profundus digitorum. They arise from the trunk of the nerve near the elbow.

The **cutaneous branch** arises from the ulnar nerve about the middle of the forearm, and divides into two branches. One branch (frequently absent) pierces the deep fascia near the wrist, and is distributed to the integument, communicating with a branch of the internal cutaneous nerve.

The second branch (**palmar cutaneous**) lies on the ulnar artery, which it accompanies to the hand, some filaments entwining round the vessel; it ends in the integument of the palm, communicating with branches of the median nerve.

The **dorsal cutaneous branch** arises about two inches above the wrist; it passes backward beneath the Flexor carpi ulnaris, perforates the deep fascia, and, along the ulnar side of the back of the wrist and hand, divides into two digital branches, of which one supplies the inner side of the little finger, and the other bifurcates to supply the adjoining sides of the little and ring fingers; it communicates with the posterior branch of the internal cutaneous nerve, and sends a communicating filament to that branch of the radial nerve which supplies the adjoining sides of the middle and ring fingers. Sometimes there is a **third** digital branch which goes to the adjacent sides of the middle and ring fingers. In this case the **radial nerve-supply** is correspondingly diminished.

The **superficial palmar branch** supplies the Palmaris brevis and the integument on the inner side of the hand, and terminates in two digital branches, which are distributed, one to the ulnar side of the little finger, the other to the adjoining sides of the little and ring fingers, the latter communicating with a branch from the median. The digital branches are distributed to the fingers in the same manner as the digital branches of the median. The **dorsal digital branches**, except those on the little finger, do not extend, as a rule, beyond the second phalanx, the remaining portion of the skin being supplied by filaments from the corresponding **palmar digital branch**.

The **deep palmar branch** passes between the Abductor and Flexor brevis minimi digiti muscles, and follows the course of the deep palmar arch beneath the flexor tendons. At its origin it supplies the muscles of the little finger. As it crosses the deep part of the hand it sends two branches to each interosseous space, one for the Dorsal and one for the Palmar interosseous muscle, the branches to the Second and Third palmar interossei supplying filaments to the two inner Lumbrical muscles. At its termination between the thumb and index finger it supplies the Adductores transversus et obliquus pollicis and the inner head of the Flexor brevis pollicis. **Articular branches** to the wrist are derived from this nerve.

The **Musculo-spiral Nerve** (Fig. 501), the largest branch of the brachial plexus, supplies the muscles of the back part of the arm and forearm and the integument of the same parts, as well as that of the back of the hand. It arises from the posterior cord of the brachial plexus by a common trunk with the circumflex
nerve, and is afterward joined by the posterior division of the trunk, formed by the junction of the eighth cervical and first dorsal nerves. It receives filaments from the sixth, seventh, and eighth cervical and first dorsal nerves. At its commencement it is placed behind the axillary and upper part of the brachial arteries, passing down in front of the tendons of the Latissimus dorsi and Teres major. It winds round the humerus in the musculo-spiral groove with the superior profunda artery, passing from the inner to the outer side of the bone, between the internal and external heads of the Triceps muscle. It pierces the external intermuscular septum, and descends between the Brachialis anticus and Supinator longus to the front of the external condyle, where it divides into the radial and posterior interosseous nerves.

The branches of the musculo-spiral nerve are—
Muscular.
Cutaneous.
Radial.
Posterior interosseous.

The muscular branches are divided into internal, posterior, and external; they supply the Triceps, Anconeus, Supinator longus, Extensor carpi radialis longior, and Brachialis anticus. These branches are derived from the nerve at the inner side, back part, and outer side of the arm.

The internal muscular branches supply the inner and middle heads of the Triceps muscle. That to the inner head of the Triceps is a long, slender filament which lies close to the ulnar nerve, as far as the lower third of the arm, and is often intimately connected with it (ulnar collateral branch).

The posterior muscular branch, of large size, arises from the nerve in the groove between the Triceps and the humerus. It divides into branches which supply the outer and inner head of the Triceps and Anconeus muscles. The branch for the latter muscle is a long, slender filament which descends in the substance of the Triceps to the Anconeus.

The external muscular branches supply the Supinator longus, Extensor carpi-radialis longior, and (usually) the outer part of the Brachialis anticus.

Fig. 501.—The suprascapular, circumflex, and musculo-spiral nerves.
The cutaneous branches are three in number, one internal and two external.

The internal cutaneous branch arises in the axillary space with the inner muscular branch. It is of small size, and passes through the axilla to the inner side of the arm, supplying the integument on its posterior aspect nearly as far as the olecranon. In its course it crosses beneath the intercosto-humeral, with which it communicates.

The two external cutaneous branches perforate the outer head of the Triceps at its attachment to the humerus. The upper and smaller one passes to the front of the elbow, lying close to the cephalic vein, and supplies the integument of the lower half of the arm on its anterior aspect. The lower branch pierces the deep fascia below the insertion of the Deltoid, and passes down along the outer side of the arm and elbow, and then along the back part of the radial side of the forearm to the wrist, supplying the integument in its course, and joining, near its termination, with the posterior cutaneous branch of the musculo-cutaneous nerve.

The radial nerve passes along the front of the radial side of the forearm to the commencement of its lower third. It lies at first a little to the outer side of the radial artery, concealed beneath the Supinator longus. In the middle third of the forearm it lies beneath the same muscle, in close relation with the outer side of the artery. It quits the artery about three inches above the wrist, passes beneath the tendon of the Supinator longus, and, piercing the deep fascia at the outer border of the forearm, divides into two branches.

The external branch, the smaller of the two, supplies the integument of the radial side and ball of the thumb, joining with the anterior branch of the musculo-cutaneous nerve.

The internal branch communicates, above the wrist, with the posterior cutaneous branch from the musculo-cutaneous, and on the back of the hand forms an arch with the dorsal cutaneous branch of the ulnar nerve. It then divides into three digital nerves, which are distributed as follows: The first supplies the ulnar side of the thumb and the radial side of the index finger; the second, the adjoining sides of the index and middle fingers; and the third, the adjacent borders of the middle and ring fingers.\(^1\) The latter nerve communicates with a filament from the dorsal branch of the ulnar nerve.

The Posterior Interosseous Nerve winds to the back of the forearm through the fibres of the Supinator brevis, and passes down, between the superficial and deep layer of muscles, to the middle of the forearm. Considerably diminished in size, it descends on the interosseous membrane, beneath the Extensor longus pollicis, to the back of the carpus, where it presents a gangliform enlargement from which filaments are distributed to the ligaments and articulations of the carpus. It supplies all the muscles of the radial and posterior brachial regions, excepting the Anconeus, Supinator longus, and Extensor carpi radialis longior.

**Surgical Anatomy.**—The brachial plexus may be ruptured by traction on the limb leading to complete paralysis. In these cases the lesion would appear to be rather a tearing away of the nerves from the spinal cord than a solution of continuity of the nerve-fibres themselves. In the axilla any of the nerves forming the brachial plexus may be injured in a wound of this part, the median being the one which is most frequently damaged from its exposed position, and the musculo-spiral, on account of its sheltered and deep position, being the least often wounded. The brachial plexus in the axilla is often damaged from the pressure of a crutch, producing the condition known as "crutch paralysis." In these cases the musculo-spiral appears to be the nerve which is most frequently implicated to the greatest extent, the ulnar nerve being the one that appears to suffer next in frequency.

The circumflex nerve is of particular surgical interest. On account of its course round the joint it is liable to be torn in fractures of the surgical neck of the humerus and in dislocations of the shoulder-joint, leading to paralysis of the deltoid, and, according to Erb, inflammation of the shoulder-joint is liable to be followed by a neuritis of this nerve from extension of the inflammation to it.

\(^1\) According to Hutchinson, the digital nerve to the thumb reaches only as high as the root of the nail; the one to the forefinger as high as the middle of the second phalanx; and the one to the middle and ring fingers not higher than the first phalangeal joint (*London Hosp. Gaz.* vol. iii. p. 312.)
THE BRACHIAL PLEXUS.

Mr. Hilton takes the circunflex nerve as an illustration of a law which he lays down, that "the same trunks of nerves whose branches supply the groups of muscles moving a joint furnish also a distribution of nerves to the skin over the insertions of the same muscles, and the interior of the joint receives its nerves from the same source." In this way he explains the fact that an inflamed joint becomes rigid, because the same nerves which supply the interior of the joint supply the muscles also which move that joint.

The median nerve is liable to injury in wounds of the forearm. When paralyzed, there is loss of flexion of the second phalanges of all the fingers and of the terminal phalanges of the index and middle fingers. Flexion of the terminal phalanges of the ring and middle fingers is effected by that portion of the Flexor profundus digitorum which is supplied by the ulnar nerve. There is power to flex the proximal phalanges through the Interossei. The thumb cannot be flexed or opposed, and is maintained in a position of extension and adduction. All power of pronation is lost. The wrist can be flexed, if the hand is first adducted, by the action of the Flexor carpi ulnaris. There is loss or impairment of sensation on the palmar surface of the thumb, index, middle, and outer half of the ring fingers, and on the dorsal surface of the same fingers over the last two phalanges; except in the thumb, where the loss of sensation would be limited to the back of the last phalanges. In order to expose the median nerve for the purpose of stretching an incision should be made along the ulnar side of the tendon of the Flexor carpi ulnaris, which serves as a guide to the nerve.

The ulnar nerve is also liable to be injured in wounds of the forearm. When paralyzed, there is loss of power of flexion in the ring and little fingers; there is impaired power of ulnar flexion and adduction; there is inability to spread out the fingers from paralysis of the Interossei; and there is inability to adduct the thumb. Sensation is lost or impaired in the skin supplied by the nerve. In order to expose the nerve in the lower part of the forearm, an incision should be made along the outer border of the tendon of the Flexor carpi ulnaris, and the nerve will be found lying on the ulnar side of the ulnar artery.

The musculo-spiral nerve is probably more frequently injured than any other nerve of the upper extremity. In consequence of its close relationship to the humerus as it lies in the musculo-spiral groove, it is frequently torn or injured in fractures of this bone; or subsequently involved in the callus that may be thrown out around a fracture, and thus pressed upon and its functions interfered with. It is also liable to be confused against the bone by kicks or blows or to be divided by wounds of the arm. When paralyzed, the hand is flexed at the wrist and lies faced. This is known as "drop-wrist." The fingers are also flexed, and on an attempt being made to extend them the last two phalanges only will be extended through the action of the Interossei, the first phalanges remaining flexed. There is no power of extending the wrist. Supination is completely lost when the forearm is extended on the arm, but it is possible to a certain extent if the forearm is flexed so as to allow of the action of the Biceps. The power of extension of the forearm is lost on account of paralysis of the Triceps. The best position in which to expose the nerve for the purpose of stretching is to make an incision along the inner border of the Supinator longus, just above the level of the elbow-joint. The skin and superficial structures are to be divided and the deep fascia exposed. The white line in this structure indicating the border of the muscle is to be defined, and the deep fascia divided in this line. By now raising the Supinator longus the nerve will be found lying beneath it, on the Brachialis anticus.

THE DORSAL NERVES (Fig. 502).

The Dorsal Nerves are twelve in number on each side. The first appears between the first and second dorsal vertebrae, and the last between the last dorsal and first lumbar.

The roots of the dorsal nerves are of small size, and vary but slightly from the second to the last. Both roots are very slender, the posterior roots only slightly exceeding the anterior in thickness. They gradually increase in length from above downward, and pass down in contact with the spinal cord for a distance equal to the height of, at least, two vertebræ, in the lower part of the dorsal region, before they emerge from the spinal canal. They then join in the intervertebral foramen, and at their exit divide into two primary divisions, a posterior (dorsal) and an anterior (intercostal).

The first and last dorsal nerves are peculiar in some respects.

Posterior Divisions of the Dorsal Nerves.

The posterior divisions of the dorsal nerves, which are smaller than the anterior, pass backward between the transverse processes, and divide into internal and external branches.

The internal branches of the six upper nerves pass inward between the Spinalis dorsi and Multifidus spine muscles, which they supply, and then, piercing
the origins of the Rhomboidei and Trapezius muscles, become cutaneous by the side of the spinous processes and ramify in the integument. The internal branches of the six lower nerves are distributed to the Multifidus spinae, without giving off any cutaneous filaments.

The external branches increase in size from above downward. They pass through the Longissimus dorsi to the cellular interval between it and the Iliocostalis, and supply those muscles, as well as their continuations upward to the head, and the Levatores costarum; the five or six lower nerves also give off cutaneous filaments, which pierce the Serratus posticus inferior and Latissimus dorsi in a line with the angles of the ribs, and then ramify in the integument.

The cutaneous branches of the dorsal nerves are twelve in number. The six upper cutaneous nerves are derived from the internal branches of the posterior divisions of the dorsal nerves. They pierce the origins of the Rhomboidei and Trapezius muscles, and become cutaneous by the side of the spinous processes, and then ramify in the integument. They are frequently furnished with gangliform enlargements. The six lower cutaneous nerves are derived from the external branches of the posterior divisions of the dorsal nerves. They pierce the Serratus posticus inferior and Latissimus dorsi in a line with the angles of the ribs, and then ramify in the integument.

Anterior Divisions of the Dorsal Nerves.

The anterior divisions of the dorsal nerves (intercostal nerves) are twelve in number on each side. They are, for the most part, distributed to the parietae of the thorax and abdomen, separately from each other, without being joined in a plexus; in which respect they differ from the other spinal nerves. Each nerve is connected with the adjoining ganglia of the sympathetic by one or two filaments. The intercostal nerves may be divided into two sets, from the difference they present in their distribution. The six upper, with the exception of the first and the intercosto-humeral branch of the second, are limited in their distribution to the parietae of the chest. The six lower supply the parietae of the chest and abdomen, the last one sending a cutaneous filament to the hip.

The First Dorsal Nerve.—The anterior division of the first dorsal nerve divides into two branches: one, the larger, leaves the thorax in front of the neck of the first rib, and enters into the formation of the brachial plexus; the other and smaller branch runs along the first intercostal space, forming the first intercostal nerve, and terminates on the front of the chest by forming the first anterior cutaneous nerve of the thorax. Occasionally this anterior cutaneous branch is wanting. The first intercostal nerve, as a rule, gives off no lateral cutaneous branch, but sometimes a small branch is given off which communicates with the intercosto-humeral.

The Upper Dorsal Nerves.—The anterior divisions of the second, third, fourth, fifth, and sixth dorsal nerves and the small branch from the first dorsal are confined to the parietae of the thorax, and are named upper or pectoral intercostal nerves. They pass forward in the intercostal spaces with the intercostal vessels, being situated below them. At the back of the chest they lie between the pleurae and the External intercostal muscle, but are soon placed between the two planes of Intercostal muscles as far as the middle of the rib. They then enter the substance of the Internal intercostal muscles, and, running amidst their fibres as far as the costal cartilages, they gain the inner surface of the muscles and lie between them and the pleurae. Near the sternum they cross the internal mammary artery and Triangularis sterni muscle, pierce the Internal intercostal and Pectoralis major muscles, and supply the integument of the front of the chest and over the mammary gland, forming the anterior cutaneous nerves of the thorax, the branch from the second nerve becoming joined with the supracleavicular nerves of the cervical plexus.

Branches.—Numerous slender muscular filaments supply the Intercostals, the Infracostales, the Levatores costarum, Serratus posticus superior, and Triangularis
THE DORSAL NERVES.

847

Fig. 502.—Superficial and deep distribution of the posterior branches of the spinal nerves (after Hirschfeld and Leveillé). On the left side the cutaneous branches are represented lying on the superficial layer of muscles. On the right side the superficial muscles have been removed, the Splenius capitis and Complexus divided in the neck, and the Erector spinae divided and partly removed in the back, so as to expose the posterior divisions of the spinal nerves near their origin. a a. Lesser occipital nerve from the cervical plexus. 1. External muscular branches of the first cervical nerve, and union by a loop with the second. 2. placed on the Rectus capitis posticus major muscle, marks the great occipital nerve, passing round the short muscles and piercing the Complexus; the external branch is seen to the outside. 3. External branch from the posterior division of the third nerve. 3'. Its internal branch, sometimes called the third occipital. 4' to 8'. The internal branches of the several corresponding nerves on the left side. The external branches of these nerves, proceeding to muscles, are displayed on the right side, d 1 to d 6, and thence to d 12. External muscular branches of the posterior divisions of the twelve dorsal nerves on the right side, d 1' to d 6'. The internal cutaneous branches of the six upper dorsal nerves on the left side, d 7' to d 12. Cutaneous twigs from the external branches of the six lower dorsal nerves. l l. External branches from the posterior divisions of several lumbar nerves on the right side, piercing the muscles, the lower descending over the gluteal region. F F. The same, more superficially, on the left side. s s. The issue and union by loops of the posterior divisions of four sacral nerves on the right side. s' s'. Some of those distributed to the skin on the left side.

sterni muscles. Some of these branches, at the front of the chest, cross the costal cartilages from one to another intercostal space.
Lateral Cutaneous Nerves.—These are derived from the intercostal nerves, midway between the vertebrae and sternum: they pierce the External intercostal and Serratus magnus muscles, and divide into two branches, anterior and posterior.

The anterior branches are reflected forward to the side and the fore part of the chest, supplying the integument of the chest and mamma and the upper digitations of the External oblique.

The posterior branches are reflected backward to supply the integument over the scapula and over the Latissimus dorsi.

The lateral cutaneous branch of the second intercostal nerve is of large size, and does not divide, like the other nerves, into an anterior and posterior branch. It is named, from its origin and distribution, the intercosto-humeral nerve (Fig. 500). It pierces the External intercostal muscle, crosses the axilla to the inner side of the arm, and joins with a filament from the nerve of Wrisberg. It then pierces the fascia, and supplies the skin of the upper half of the inner and back part of the arm, communicating with the internal cutaneous branch of the musculo-spiral nerve. The size of this nerve is in inverse proportion to the size of the other cutaneous nerves, especially the nerve of Wrisberg. A second intercosto-humeral nerve is frequently given off from the third intercostal. It supplies filaments to the armpit and inner side of the arm.

The Lower Dorsal Nerves.—The anterior divisions of the seventh, eighth, ninth, tenth, and eleventh dorsal nerves are continued anteriorly from the intercostal spaces into the abdominal wall, hence these nerves are named lower or abdominal intercostal nerves; the twelfth dorsal is continued throughout its whole course in the abdominal wall, since it is placed below the last rib (subcostal nerve). They have (except the last) the same arrangement as the upper ones as far as the anterior extremities of the intercostal spaces, where they pass behind the costal cartilages, and between the Internal oblique and Transversalis muscles, to the sheath of the Rectus, which they perforate. They supply the Rectus muscle, and terminate in branches which become subcutaneous near the linea alba. These branches are named the anterior cutaneous nerves of the abdomen. They are directed outward as far as the lateral cutaneous nerves, supplying the integument of the front of the belly. The lower intercostal nerves supply the Intercostals, Serratus posticus inferior, and Abdominal muscles. Filaments have been traced to the costal part of the Diaphragm. About the middle of their course they give off lateral cutaneous branches, which pierce the External intercostal and External oblique muscles, in the same line as the lateral cutaneous nerves of the thorax, and divide into anterior and posterior branches, which are distributed to the integument of the abdomen and back, the anterior branches passing nearly as far forward as the margin of the Rectus, the posterior branches passing backward to supply the skin over the Latissimus dorsi, where they join the dorsal cutaneous nerves.

The last dorsal is larger than the other dorsal nerves. Its anterior division runs along the lower border of the last rib in front of the Quadratus lumborum. perforates the Transversalis, and passes forward between it and the Internal oblique to be distributed in the same manner as the lower intercostal nerves. It communicates with the ilio-hypogastric branch of the lumbar plexus, and is frequently connected with the first lumbar nerve by a slender branch, the dorso-lumbar nerve, which descends in the substance of the Quadratus lumborum.

The lateral cutaneous branch of the last dorsal is remarkable for its large size: it perforates the Internal and External oblique muscles, passes downward over the crest of the ilium in front of the iliac branch of the ilio-hypogastric (Fig. 509), and is distributed to the integument of the front of the hip, some of its filaments extending as low down as the trochanter major. It does not divide into an anterior and posterior branch like the other lateral cutaneous branches of the intercostal nerves.

Surgical Anatomy.—The lower seven intercostal nerves and the ilio-hypogastric from the first lumbar nerve supply the skin of the abdominal wall. They run downward and inward
fairly equidistant from each other. The sixth and seventh supply the skin over the "pit of the stomach; the eighth corresponds to about the position of the middle linea transversa; the tenth to the umbilicus; and the ilio-hypogastric supplies the skin over the pubes and external abdominal rim. There are several points of surgical importance about the distribution of these nerves, and it is important to remember their origin and course, for in many diseases affecting the nerve-trunks at or near the origin the pain is referred to their peripheral terminations. Thus in Pott's disease of the spine children will often be brought to the surgeon suffering from pain in the belly. This is due to the fact that the nerves are irritated at the seat of disease as they issue from the spinal canal. When the irritation is confined to a single pair of nerves, the sensation complained of is often a feeling of constriction, as if a cord were tied round the abdomen; and in these cases the situation of the sense of constriction may serve to localize the disease in the spinal column. In other cases, where the bone disease is more extensive and two or more nerves are involved, a more general diffused pain in the abdomen is complained of. A similar condition is sometimes present in affections of the cord itself, as in tabes dorsalis.

Again, it must be borne in mind that the same nerves which supply the skin of the abdomen supply also the planes of muscle which constitute the greater part of the abdominal wall. Hence it follows that any irritation applied to the peripheral terminations of the cutaneous branches in the skin of the abdomen is immediately followed by reflex contraction of the abdominal muscles. A good practical illustration of this may sometimes be seen in watching two surgeons examine the abdomen of the same patient. One, whose hand is cold, causes the muscles of the abdominal wall to at once contract and the belly to become rigid, and thus not nearly so suitable for examination: the other, who has taken the precaution to warm his hand, examines the abdomen without exciting any reflex contraction. The supply of both muscles and skin from the same source is of importance in protecting the abdominal viscera from injury. A blow on the abdomen, even of a severe character, will do no injury to the viscera if the muscles are in a condition of firm contraction; whereas in cases where the muscles have been taken unawares, and the blow has been struck while they were in a state of rest, an injury insufficient to produce any lesion of the abdominal wall has been attended with rupture of some of the abdominal contents. The importance, therefore, of immediate reflex contraction upon the receipt of an injury cannot be overestimated, and the intimate association of the cutaneous and muscular fibres in the same nerve produces a much more immediate response on the part of the muscles to any peripheral stimulation of the cutaneous filaments than would be the case if the two sets of fibres were derived from independent sources.

Again, the nerves supplying the abdominal muscles and skin derived from the lower intercostal nerves are intimately connected with the sympathetic supplying the abdominal viscera through the lower thoracic ganglia from which the splanchic nerves are derived. In consequence of this, in laceration of the abdominal viscera and in acute peritonitis the muscles of the belly-wall become firmly contracted, and thus as far as possible preserve the abdominal contents in a condition of rest.

**THE LUMBAR NERVES.**

The lumbar nerves are five in number on each side. The first appears between the first and second lumbar vertebrae, and the last between the last lumbar and the base of the sacrum.

The roots of the lower lumbar (and upper sacral) nerves are the largest, and their filaments the most numerous, of all the spinal nerves, and they are closely aggregated together upon the lower end of the cord. The anterior roots are the smaller, but there is not the same disproportion between them and the posterior roots as in the cervical nerves. The roots of these nerves have a vertical direction, and are of considerable length, more especially the lower ones, since the spinal cord does not extend beyond the first lumbar vertebra. The roots become joined in the intervertebral foramina, and the nerves so formed divide at their exit into two divisions, posterior and anterior.

**Posterior Divisions of the Lumbar Nerves.**

The posterior divisions of the lumbar nerves (Fig. 502) diminish in size from above downward; they pass backward beneath the transverse processes, and divide into internal and external branches.

The internal branches, the smaller, pass inward close to the articular processes of the vertebrae, and supply the Multifidus spine and Interspinales muscles.

The external branches supply the Erector spine and Interspinalis muscles. From the three upper branches cutaneous nerves are derived which pierce the aponeurosis of the Latissimus dorsi muscle and descend over the back part of the
crested on the ilium, to be distributed to the integument of the gluteal region, some of the filaments passing as far as the trochanter major (\textit{nervi clunium superiores}).

**Anterior Divisions of the Lumbar Nerves.**

The anterior divisions of the lumbar nerves increase in size from above downward. At their origin they communicate with the lumbar ganglia of the sympathetic by long, slender filaments, which accompany the lumbar arteries round the sides of the bodies of the vertebrae, beneath the Psoas muscle. The nerves pass obliquely outward behind the Psoas magnus or between its fasciculi, distributing filaments to it and the Quadratus lumborum. The anterior divisions of the four upper nerves give off their branches by a series of anastomotic loops, which are called the \textit{lumbar plexus}. The anterior division of the fifth lumbar, joined with a branch from the fourth, descends across the base of the sacrum to join the anterior division of the first sacral nerve and assist in the formation of the sacral plexus. The cord resulting from the union of the fifth lumbar and the branch from the fourth is called the \textit{lumbo-sacral nerve}.

**The Lumbar Plexus.**

The \textit{lumbar plexus}, so called, is formed by the anastomotic loops above mentioned. The plexus is narrow above, and often connected with the last dorsal by a slender branch, the \textit{dorso-lumbar nerve}; it is broad below, where it is joined to the sacral plexus by the lumbo-sacral cord. It is situated in the substance of the Psoas muscle near its posterior part, in front of the transverse processes of the lumbar vertebrae.

The mode in which the plexus is formed varies greatly in different subjects. A plan which is often found is the following: The \textit{first lumbar nerve} receives a branch from the last dorsal, and gives off two branches, the upper of which sub-

![Fig. 503.—Plan of the lumbar plexus.](image-url)
divides into the ilio-hypogastric and ilio-inguinal; the lower one descends and subdivides into two branches, an anterior and a posterior. The second lumbar nerve sends a branch to join with the anterior of the two preceding, to form the genito-crural nerve; the rest of the nerve then receives the posterior of the two above mentioned, and proceeds downward, giving off an external, a middle, and an internal branch. The third lumbar nerve gives off three branches, known as dorsal, middle, and ventral. The fourth lumbar nerve also divides into three branches, known as anterior, posterior, and inferior. These various subdivisions now unite as follows: The external from the second joins the dorsal from the third to form the external cutaneous nerve. The middle branches from the second and third together with the posterior from the fourth, unite to form the anterior crural nerve; while the remaining (internal and ventral) branches of the second and third lumbar nerves unite with the anterior of the fourth to form the obturator nerve. The remainder of the anterior division of the fourth nerve passes down to communicate with the fifth lumbar nerve. The accessory obturator, when it exists, is formed by a small branch from the third nerve joining with a small branch from the fourth.

From this arrangement it follows that the ilio-hypogastric and ilio-inguinal are derived entirely from the first lumbar nerve; the genito-crural from the first and second nerves; the external cutaneous from the second and third; the anterior crural and obturator by fibres derived from the second, third, and fourth; and the accessory obturator, when it exists, from the third and fourth.

The branches of the lumbar plexus are—the

| Ilio-hypogastric. | Anterior crural. |
| Ilio-inguinal. | Obturator. |
| Genito-crural. | Accessory obturator. |
| External cutaneous. |

The Ilio-hypogastric Nerve (superior musculo-cutaneous) arises from the first lumbar nerve. It emerges from the outer border of the Psoas muscle at its upper part, and crosses obliquely in front of the Quadratus lumborum to the crest of the ilium. It then perforates the Transversalis muscle at its posterior part, near the crest of the ilium, and divides between it and the Internal oblique into two branches, iliac and hypogastric.

The iliac branch pierces the Internal and External oblique muscles immediately above the crest of the ilium, and is distributed to the integument of the gluteal region, behind the lateral cutaneous branch of the last dorsal nerve (Fig. 509). The size of this nerve bears an inverse proportion to that of the cutaneous branch of the last dorsal nerve.

The hypogastric branch (Fig. 505) continues onward between the Internal oblique and Transversalis muscles. It then pierces the Internal oblique, and near the middle line perforates the aponeurosis of the External oblique, about an inch above and a little to the outer side of the external abdominal ring, and is distributed to the integument of the hypogastric region.

The ilio-hypogastric nerve communicates with the last dorsal and ilio-inguinal nerves.

The Ilio-inguinal Nerve (inferior musculo-cutaneous), smaller than the preceding, arises with it from the first lumbar nerve. It emerges from the outer border of the Psoas just below the ilio-hypogastric, and, passing obliquely across the Quadratus lumborum and Iliacus muscles, perforates the Transversalis near the fore part of the crest of the ilium, and communicates with the ilio-hypogastric nerve between that muscle and the Internal oblique. The nerve then pierces the Internal oblique, distributing filaments to it; and, accompanying the spermatic cord through the inguinal canal, it escapes at the external abdominal ring, and is distributed to the integument of the upper and inner part of the thigh, and to the scrotum in the male and to the labium in the female. The size of this nerve is in
inverse proportion to that of the ilio-hypogastric. Occasionally it is very small, and ends by joining the ilio-hypogastric; in such cases a branch from the ilio-hypogastric takes the place of the ilio-inguinal, or the latter nerve may be altogether absent.

The Genito-crural Nerve arises from the first and second lumbar nerves. It passes obliquely through the substance of the Psoas, and emerges from its inner border at a level corresponding to the intervertebral substance between the third and fourth lumbar vertebrae. It descends on its surface for a variable distance, and divides into a genital and crural branch.

The genital branch passes outward on the Psoas magnus, near the external iliac artery, to which it gives a twig. It then pierces the fascia transversalis or passes through the internal abdominal ring, descends along the back part of the spermatic cord to the scrotum in the male, and supplies the Cremaster muscle. In the female it accompanies the round ligament.

The crural branch descends on the external iliac artery, sending a few filaments round it, and, passing beneath Poupart's ligament into the thigh, enters the sheath of the femoral vessels lying superficial and a little external to the femoral artery, to which it also supplies a few filaments. It pierces the anterior layer of the sheath of the vessels, and, becoming superficial by passing through the fascia lata, it supplies the skin of the anterior aspect of the thigh as far as midway between the pelvis and knee. On the front of the thigh it communicates with the outer branch of the middle cutaneous nerve, derived from the anterior crural.
The External Cutaneous Nerve arises from the second and third lumbar nerves. It emerges from the outer border of the Psoas muscle about its middle, and
crosses the Iliacus muscle obliquely, to the notch immediately beneath the anterior superior spine of the ilium, where it passes under Poupart's ligament into the thigh, and divides into two branches, anterior and posterior.

The anterior branch descends in an aponeurotic canal formed in the fascia lata, becomes superficial about four inches below Poupart's ligament, and divides into branches which are distributed to the integument along the anterior and outer part of the thigh, as far down as the knee. This nerve occasionally communicates with a branch of the long saphenous nerve in front of the knee-joint.

The posterior branch pierces the fascia lata, and subdivides into branches which pass backward across the outer and posterior surface of the thigh, supplying the integment from the crest of the ilium as far as the middle of the thigh.

The Obturator Nerve supplies the obturator externus and Adductor muscles of the thigh, the articulations of the hip and knee, and occasionally the integument of the thigh and leg. It arises by three branches—from the second, the third, and the fourth lumbar nerves. It descends through the inner fibres of the Psoas muscle and emerges from its inner border near the brim of the pelvis; it then runs along the lateral wall of the pelvis, above the obturator vessels, to the upper part of the obturator foramen, where it enters the thigh, and divides into an anterior and a posterior branch, separated by some of the fibres of the Obturator externus, and lower down by the Adductor brevis muscle.

The anterior branch (Fig. 506) passes down in front of the Adductor brevis, being covered by the Pectineus and Adductor longus, and at the lower border of the latter muscle communicates with the internal cutaneous and internal saphenous nerves, forming a kind of plexus. It then descends upon the femoral artery, upon which it is finally distributed. The nerve, near the obturator foramen, gives off an articular branch to the hip-joint. Behind the Pectineus it distributes muscular branches to the Adductor longus and Gracilis, occasionally to the Adductor brevis, and rarely to the Pectineus, and receives a communicating branch from the accessory obturator nerve.

Occasionally the communicating branch to the internal cutaneous and internal saphenous nerves is continued down, as a cutaneous branch, to the thigh and leg. When this is so, this occasional cutaneous branch emerges from beneath the lower border of the Adductor longus, descends along the posterior margin of the Sartorius to the inner side of the knee, where it pierces the deep fascia, communicates with the long saphenous nerve, and is distributed to the integument of the inner side of the leg as low down as its middle. When this communicating branch is small, its place is supplied by the internal cutaneous nerve.

The posterior branch of the obturator nerve pierces the Obturator externus, sending branches to supply it, and passes behind the Adductor brevis on the front of the Adductor magnus, where it divides into numerous muscular branches, which supply the Adductor magnus, and occasionally the Adductor brevis. One of the branches gives off a filament to the knee-joint.

The articular branch for the knee-joint perforates the lower part of the Adductor magnus and enters the popliteal space; it then descends upon the popliteal artery as far as the back part of the knee-joint, where it perforates the posterior ligament, and is distributed to the synovial membrane. It gives filaments to the artery in its course.

The Accessory Obturator Nerve (Fig. 504) is not constantly present. It is of small size, and arises by separate filaments from the third and fourth lumbar nerves. It descends along the inner border of the Psoas muscle, crosses the horizontal ramus of the os pubis, and passes under the outer border of the Pectineus muscle, where it divides into numerous branches. One of these supplies the Pectineus, penetrating its under surface; another is distributed to the hip-joint; while a third communicates with the anterior branch of the obturator nerve. When this nerve is absent the hip-joint receives two branches from the obturator nerve. Occasionally it is very small, and becomes lost in the capsule of the hip-joint.
The **Anterior Crural Nerve** (Figs. 504, 506) is the largest branch of the lumbar plexus. It supplies muscular branches to the Iliacus, Pectineus, and all the muscles on the front of the thigh, excepting the Tensor vaginae femoris; cutaneous filaments to the front and inner side of the thigh and to the leg and foot; and articular branches to the hip and knee. It arises from the second, third, and fourth lumbar nerves. It descends through the fibres of the Psoas muscle, emerging from it at the lower part of its outer border, and passes down between it and the Iliacus, and beneath Poupart's ligament, into the thigh, where it becomes somewhat flattened, and divides into an anterior part which passes superficial to the external circumflex vessels, and a posterior part which passes beneath these vessels. Under Poupart's ligament it is separated from the femoral artery by the Psoas muscle, and lies beneath the iliac fascia.

Within the pelvis the anterior crural nerve gives off from its outer side some small branches to the Iliacus, and a branch to the femoral artery which is distributed upon the upper part of that vessel. The origin of this branch varies: it occasionally arises higher than usual, or it may arise lower down in the thigh.

**External to the pelvis** the following branches are given off:

**From the Anterior Division.**
- Middle cutaneous.
- Internal cutaneous.
- Muscular.

**From the Posterior Division.**
- Long saphenous.
- Muscular.
- Articular.

**Anterior Division.—** The *middle cutaneous nerve* (Fig. 505) pierces the fascia lata about three inches below Poupart's ligament, and divides into two branches, which descend in immediate proximity along the fore part of the thigh, distributing numerous branches to the integument as low as the front of the knee, where it communicates with the *nervus cutaneus patella*, a branch of the internal saphenous nerve, helping to form the patellar plexus. Its outer branch communicates, above, with the crural branch of the genito-crural nerve, and the inner branch with the internal cutaneous nerve below. The Sartorius muscle is frequently pierced by this nerve or by its outer branch.

The *internal cutaneous nerve* passes obliquely across the upper part of the sheath of the femoral artery, and divides in front or at the inner side of that vessel into two branches, anterior and posterior or internal.

The *anterior branch* runs downward on the Sartorius, perforates the fascia lata at the lower third of the thigh, and divides into two branches, one of which supplies the integument as low down as the inner side of the knee; the other crosses to the outer side of the patella, communicating in its course with the *nervus cutaneus patella*, a branch of the internal saphenous nerve.

The *posterior or internal branch* descends along the inner border of the Sartorius muscle to the knee, where it pierces the fascia lata, communicates with the long saphenous nerve, and gives off several cutaneous branches. The nerve then passes down the inner side of the leg, to the integument of which it is distributed. This nerve, beneath the fascia lata, at the lower border of the Adductor longus, joins in a plexiform network by uniting with branches of the long saphenous and obturator nerves (Fig. 506). When the communicating branch from the obturator nerve is large and continued to the integument of the leg, the inner branch of the internal cutaneous is small and terminates at the plexus, occasionally giving off a few cutaneous filaments.

The internal cutaneous nerve, before dividing, gives off a few filaments, which pierce the fascia lata, to supply the integument of the inner side of the thigh, accompanying the long saphenous vein. One of these filaments passes through the saphenous opening; a second becomes subcutaneous about the middle of the thigh; and a third pierces the fascia at its lower third.

The *muscular branches* supply the Pectineus and Sartorius. Those to the Pectineus, often united with the internal cutaneous nerve at their origin, are
usually two in number and pass inward behind the femoral vessels, and enter the muscle on its anterior surface. Sometimes one of these nerves is given off in the pelvis, and is then often united with the accessory obturator. The Sartorius is supplied by filaments which arise in common with the middle cutaneous nerve and enter the upper part of the muscle.

**Posterior Division.**—The long or internal saphenous nerve is the largest of the cutaneous branches of the anterior crural. It approaches the femoral artery where this vessel passes beneath the Sartorius, and lies at first on its outer side and then crosses over it, beneath the aponeurotic covering of Hunter's canal, as far as the opening in the lower part of the Adductor magnus. It then quits the artery, and descends vertically along the inner side of the knee, beneath the Sartorius, pierces the fascia lata, opposite the interval between the tendons of the Sartorius and Gracilis, and becomes subcutaneous. The nerve then passes along the inner side of the leg, accompanied by the internal saphenous vein, descends behind the internal border of the tibia, and, at the lower third of the leg, divides into two branches: one continues its course along the margin of the tibia, terminating at the inner ankle; the other passes in front of the ankle, and is distributed to the integument along the inner side of the foot, as far as the great toe, communicating with the internal branch of the musculo-cutaneous nerve.

The long saphenous nerve *about the middle of the thigh* gives off a communicating branch which joins the plexus formed by the obturator and internal cutaneous nerves.

*At the inner side of the knee* it gives off a large branch (*nervus cutaneus patella*) which pierces the Sartorius and fascia lata, and is distributed to the integument in front of the patella. This nerve communicates above the knee with the anterior branch of the internal cutaneous and with the middle cutaneous; below the knee, with other branches of the long saphenous; and on the outer side of the joint, with branches of the external cutaneous nerve, forming a plexiform network, the *plexus patellae*. The cutaneous nerve of the patella is occasionally small, and terminates by joining the internal cutaneous, which supplies its place in front of the knee.

*Below the knee* the branches of the long saphenous nerve are distributed to the integument of the front and inner side of the leg, communicating with the cutaneous branches from the internal cutaneous or from the obturator nerve.

The **muscular branches** are as follows:

- **The branch to the Rectus muscle** enters its under surface high up, sending off a small filament to the hip-joint.

- **The branch to the Vastus externus**, of large size, follows the course of the descending branch of the external circumflex artery to the lower part of the muscle. It gives off an articular filament to the knee-joint.

- **The branch to the Vastus internus** is a long branch which runs down on the outer side of the femoral vessels in company with the internal saphenous nerve for its upper part. It enters the muscle about its middle, and gives off a filament which can usually be traced downward on the surface of the muscle to the knee-joint.

- **The branch to the Crureus** enters the muscle on its anterior surface about the middle of the thigh, and sends a filament through the muscle to the Subcrureus. **Articular branches to the hip-joint** are derived from some of the other muscular branches as well as from the nerve to the Rectus.

- **The articular branches to the knee-joint** are two in number. One, a long, slender filament, is derived from the nerve to the Vastus externus. It penetrates the capsular ligament of the joint on its anterior aspect. The other is derived from the nerve to the Vastus internus. It can usually be traced downward on the surface of this muscle to near the joint; it then penetrates the muscular fibres, and accompanies the deep branch of the anastomoticca magna artery, pierces the capsular ligament of the joint on its inner side, and supplies the synovial membrane.
THE SACRAL AND COCCYGEAL NERVES.

The sacral nerves are five in number on each side. The four upper ones pass from the sacral canal through the sacral foramina; the fifth through the foramen between the sacrum and coccyx.

The roots of origin of the upper sacral (and lower lumbar) nerves are the largest of all the spinal nerves, whilst those of the lowest sacral and coccygeal nerve are the smallest.

The roots of these nerves are of very considerable length, being longer than those of any of the other spinal nerves, on account of the spinal cord not extending beyond the first lumbar vertebra. From their great length and the appearance they present in connection with the spinal cord the roots of origin of these nerves are called collectively the cauda equina. Each sacral and coccygeal nerve divides into two divisions, posterior and anterior.

The posterior divisions of the sacral nerves (Fig. 507) are small, diminish in size from above downward, and emerge, except the last, from the sacral canal by the posterior sacral foramina.

The three upper ones are covered, at their exit from the sacral canal, by the Multifidus spinae, and divide into internal and external branches.

The internal branches are small, and supply the Multifidus spinae.

The external branches join with one another and with the last lumbar and fourth sacral nerves by means of communicating loops. These branches pass outward to the outer surface of the great sacro-sciatic ligament, where they form a second series of loops beneath the Gluteus maximus. Cutaneous branches from this second series of loops, usually three in number, pierce the Gluteus maximus: one near the posterior inferior spine of the ilium; another opposite the end of the sacrum; and the third midway between the other two. They supply the integument over the posterior part of the gluteal region (nervi clunium medii).
The posterior divisions of the two lower sacral nerves are situated below the Multifidus spine. They are of small size, and do not divide into internal and external branches, but join with each other, and with the coccygeal nerve, so as to form loops on the back of the sacrum, filaments from which supply the Extensor coccygis and the integument over the coccyx.

The coccygeal nerve divides into its anterior and posterior divisions in the spinal canal. The posterior division is the smaller. It does not divide, but receives, as already mentioned, a communicating branch from the last sacral, and is lost in the fibrous structure on the back of the coccyx.

The anterior divisions of the sacral nerves diminish in size from above down-ward. The four upper ones emerge from the anterior sacral foramina: the anterior division of the fifth, after emerging from the spinal canal through its terminal opening, curves forward between the sacrum and the coccyx. All the anterior sacral nerves communicate with the sacral ganglia of the sympathetic at their exit from the sacral foramina. The first nerve, of large size, unites with the lumbo-sacral cord, formed by the fifth lumbar, and a branch from the fourth lumbar. The second, equal in size to the preceding, and the third, about one-fourth the size of the second, unite, together with a small fasciculus from the fourth, to form the sacral plexus, a visceral branch being given off from the third nerve to the bladder.

The fourth anterior sacral nerve sends a branch to join the sacral plexus. The remaining portion of the nerve divides into visceral and muscular branches, and a communicating filament descends to join the fifth sacral nerve. The visceral branches are distributed to the viscera of the pelvis, communicating with the sympathetic nerve. These branches ascend upon the rectum and bladder, and in the female upon the vagina, communicating with branches of the sympathetic from the pelvic plexus. The muscular branches are distributed to the Levator...
ani, Coccygeus, and Sphincter ani. The branch to the Sphincter ani pierces the Levator ani, so as to reach the ischio-rectal fossa, where it is found lying in front of the coccyx. Cutaneous filaments arise from the latter branch, which supply the integument between the anus and coccyx. Another cutaneous branch is frequently given off from this nerve, though sometimes from the pudic (Schwalbe). It perforates the great sacro-sciatic ligament, and, winding round the lower border of the Gluteus maximus, supplies the skin over the lower and inner part of this muscle.

The fifth anterior sacral nerve, after passing from the lower end of the sacral canal, curves forward through the fifth sacral foramen, formed between the lower part of the sacrum and the transverse process of the first piece of the coccyx. It pierces the Coccygeus muscle, and descends upon its anterior surface to near the tip of the coccyx, where it again perforates the muscle, to be distributed to the integument over the back part and side of the coccyx. This nerve communicates above with the fourth sacral and below with the coccygeal nerve, and supplies the Coccygeus muscle.

The anterior division of the coccygeal nerve is a delicate filament which escapes at the termination of the sacral canal; it passes downward behind the rudimentary transverse process of the first piece of the coccyx, and curves forward through the notch between the first and second pieces, piercing the Coccygeus muscle, and descending on its anterior surface to near the tip of the coccyx, where it again pierces the muscle, to be distributed to the integument over the back part and side of the coccyx. It is joined by a branch from the fifth anterior sacral as it descends on the surface of the Coccygeus muscle.

The Sacral Plexus (Fig. 508).

The sacral plexus is formed by the lumbo-sacral cord, the anterior divisions of the three upper sacral nerves, and part of that of the fourth. These nerves proceed in different directions; the upper ones obliquely downward and outward, the lower ones nearly horizontally. The sacral plexus is triangular in form, its base corresponding with the exit of the nerves from the sacrum, its apex with the lower part of the great sacro-sciatic foramen. It rests upon the anterior surface of the Pyriformis, and is covered in front by the pelvic fascia, which separates it from the sciatic and pudic branches of the internal iliac artery and from the viscera of the pelvis.

The special method of the formation of the plexus is as follows: The lumbo-sacral cord, first, second and larger part of the third sacral nerves unite to form a large upper cord or band. The smaller part of the third, together with the branch of the fourth nerve, already mentioned as going to the sacral plexus, unite to form a smaller, lower, cord or band. The larger is continued into the great sciatic nerve; the smaller is continuous with the pudic nerve. The remaining branches of the plexus are derived separately or by more or less intercommunication from the sacral nerves before the latter form the two principal cords just mentioned.

The branches of the sacral plexus are—

The muscular branches supply the Pyriformis, Obturator internus, the two Gemelli, and the Quadratus femoris. The branches to the Pyriformis arise from the back of the first and second sacral nerves before they enter the plexus; the branch to the Obturator internus arises from the lumbo-sacral and first two sacral nerves: it passes out of the pelvis through the great sacro-sciatic foramen, crosses the spine of the ischium, and re-enters the pelvis through the lesser sacro-sciatic foramen to the inner surface of the Obturator internus; the branch to the Gemellus superior arises in common with the nerve to the Obturator internus; it

1 N. B.—In this diagram the external saphenous and communicans peronei are not in their normal position. They have been displaced by the removal of the superficial muscles.
enters the muscle at the upper part of its posterior surface; the small branch to the Gemellus inferior and Quadratus femoris arises from the lumbo-sacral cord and first sacral nerve: it passes through the great sacro-sciatic foramen, and courses down beneath the Gemelli and tendon of the Obturator internus, and supplies the muscles on their deep or anterior surface. It gives off an articular branch to the hip-joint. Another articular branch is occasionally derived from the upper part of the great sciatic nerve.

The Superior Gluteal Nerve (Fig. 510) arises from the back part of the lumbo-sacral cord and first sacral nerve: it passes from the pelvis through the great sacro-sciatic foramen above the Pyriformis muscle, accompanied by the gluteal vessels, and divides into a superior and an inferior branch.

The superior branch follows the line of origin of the Gluteus minimus, and supplied the Gluteus medius.

The inferior branch crosses obliquely between the Gluteus minimus and medius, distributing filaments to both these muscles, and terminates in the Tensor vaginae femoris, extending nearly to its lower end.

The Inferior Gluteal arises from the lumbo-sacral cord and first and second sacral nerves, and is often intimately connected with the small sciatic at its origin. It passes out of the pelvis through the great sciatic notch, beneath the Pyriformis muscle, and, dividing into a number of branches, enters the Gluteus maximus muscle on its under surface.

The Perforating Cutaneous Nerve is derived from the second and third sacral nerves. It pierces the great sacro-sciatic ligament and winds round the lower border of the Gluteus maximus muscle to supply the skin of the buttock.

The Pudic Nerve arises from the lower cord of the sacral plexus (sometimes containing fibres derived from the second and even first sacral nerves), and leaves the pelvis, through the great sacro-sciatic foramen, below the Pyriformis. It then crosses the spine of the ischium, and re-enters the pelvis through the lesser sacro-sciatic foramen. It accompanies the pudic vessels upward and forward for a short distance along the outer wall of the ischio-rectal fossa, and then divides into three branches, the perineal nerve, the dorsal nerve of the penis, and the inferior hemorrhoidal nerve.

The inferior hemorrhoidal nerve is occasionally derived separately from the sacral plexus. It passes across the ischio-rectal fossa, with its accompanying vessels, toward the lower end of the rectum, and is distributed to the integument round the anus. Branches of this nerve communicate with the inferior pudendal and superficial perineal nerves at the fore part of the perineum.

The perineal nerve, the largest of the branches of the pudic, is situated below the pudic artery. It accompanies the superficial perineal artery in the perineum, dividing into cutaneous and muscular branches.

The cutaneous branches (superficial perineal) are two in number, posterior and anterior. The posterior or external branch passes forward along the outer side of the perineal space parallel to the inferior pudendal nerve, and is distributed to the skin of the scrotum. It communicates with the inferior hemorrhoidal, the inferior pudendal, and the other superficial perineal nerve. The anterior or internal branch passes forward nearer to the middle line, to be distributed to the inner and back part of the scrotum. Both these nerves supply the labia majora in the female.

The muscular branches are distributed to the Transversus perinæi, Accelerator urinæ, Erector penis, External sphincter and Levator ani, and Compressor urethrae. A distinct branch is given off from the nerve to the Accelerator urinæ, which pierces this muscle and supplies the corpus spongiosum, ending in the mucous membrane of the urethra. This is the nerve to the bulb.

The dorsal nerve of the penis is the deepest division of the pudic nerve; it accompanies the pudic artery along the ramus of the ischium: piercing the posterior layer of the deep perineal fascia, it runs forward along the inner margin of the ramus of the os pubis, between the two layers of the deep fascia. It then
pierces the anterior layer, and, in company with the dorsal artery of the penis, passes through the suspensory ligament, and, running forward, is distributed to the glans. On the penis this nerve gives off a cutaneous branch which runs along the side of the organ; it is joined with branches of the sympathetic, and supplies the integument of the upper surface and sides of the penis and prepuce, giving a large branch to the corpus cavernosum.

In the female the dorsal nerve is very small and supplies the elitoris.

The **Small Sciatic Nerve** (Fig. 510) supplies the integument of the perineum and back part of the thigh and leg. It is usually formed by the union of three branches, which arise from the first, second, and third nerves of the sacral plexus. It issues from the pelvis through the great sacro-sciatic foramen below the Pyriformis muscle, descends beneath the Gluteus maximus with the sciatic artery, and at the lower border of that muscle passes along the back part of the thigh, beneath the fascia lata, to the lower part of the popliteal region, where it pierces the fascia and becomes cutaneous. It then accompanies the external saphenous vein to about the middle of the leg, its terminal filaments communicating with the external saphenous nerve.

The branches of the small sciatic nerve are all cutaneous, and are as follows: perineal, femoral, and ascending.

The **perineal cutaneous branches** are distributed to the skin at the upper and inner side of the thigh, on its posterior aspect, and to the perineum. One branch, longer than the rest, the **inferior pudendal**, curves forward below the tuber ischii, pierces the fascia lata, and passes forward beneath the superficial fascia of the perineum to be distributed to the integument of the scrotum in the male and the labium in the female, communicating with the superficial perineal and inferior haemorrhoidal nerves.

The **femoral cutaneous branches** consist of filaments, which are derived from both sides of the nerve and are distributed to the skin of the inner and outer side of the thigh on its posterior aspect, as far down as the middle of that region, and also to the skin of the back part of the thigh, popliteal region, and upper part of the leg.

The **ascending cutaneous branches** consist of two or three filaments, which turn upward round the lower border of the gluteus maximus, to supply the integument covering its surface (*nervi cutanei inferioriores*).

The **Great Sciatic Nerve** (Fig. 510) supplies nearly the whole of the integments of the leg, the muscles of the back of the thigh, and those of the leg and foot. It is the largest nervous cord in the body, measuring three-quarters of an inch in breadth, and is the continuation of the lower cord of the sacral plexus. It passes out of the pelvis through the great sacro-sciatic foramen, below the Pyriformis muscle. It descends between the trochanter major and tuberosity of the ischium, along the back part of the thigh to about its lower third, where it divides into two large branches, the **internal and external popliteal nerves**.

This division may take place at any point between the sacral plexus and the lower third of the thigh. When the division occurs at the plexus, the two nerves descend together, side by side; or they may be separated at their commencement by the interposition of part or the whole of the Pyriformis muscle. As the nerve descends along the back of the thigh it rests at first upon the External rotator muscles, in company with the small sciatic nerve and artery, being covered by the Gluteus maximus; lower down, it lies upon the Adductor magnus and is covered by the long head of the Biceps.

The **branches** of the nerve, before its division, are articular and muscular.

The **articular branches** arise from the upper part of the nerve; they supply the hip-joint, perforating its fibrous capsule posteriorly. These branches are sometimes derived from the sacral plexus.

The **muscular branches** are distributed to the Flexors of the leg—viz. the Biceps, Semitendinosus, and Semimembranosus, and a branch to the Adductor magnus. These branches are given off beneath the Biceps muscle.
The **Internal Popliteal Nerve**, the larger of the two terminal branches of the great sciatic, descends along the back part of the thigh, through the middle of the popliteal space, to the lower border of the Popliteus muscle, where it passes with the artery beneath the arch of the Soleus and becomes the posterior tibial. It is overlapped by the hamstring muscles above, and then becomes more superficial, and lies to the outer side of, and some distance from, the popliteal vessels; opposite the knee-joint it is in close relation with the vessels, and crosses to the inner side of the artery. Below, it is overlapped by the Gastrocnemius.

The **branches** of this nerve are—articular, muscular, and a cutaneous branch, the *communicans poplitei* nerve.

The **articular branches**, usually three in number, supply the knee-joint: two of these branches accompany the superior and inferior internal articular arteries, and a third, the azygous articular artery.

The **muscular branches**, four or five in number, arise from the nerve as it lies between the two heads of the Gastrocnemius muscle; they supply that muscle, the Plantaris, Soleus, and Popliteus. The filaments which supply the Popliteus turn round its lower border and are distributed to its deep surface.

The *communicans poplitei* descends between the two heads of the Gastrocnemius muscle, and about the middle of the back of the leg pierces the deep fascia, and joins a communicating branch (*communicans peronei*) from the external popliteal nerve to form the external or short saphenous (Fig. 509). The external saphenous nerve, formed by the cutaneous branches of the internal and external popliteal nerves, passes downward and outward near the outer margin of the tendon Achilles, lying close to the external saphenous vein, to the interval between the external malleolus and the os calcis. It winds round the outer malleolus, and is distributed to the integument along the outer side of the foot and little toe, communicating on the dorsum of the foot with the musculo-cutaneous nerve. In the leg its branches communicate with those of the small sciatic.

The **Posterior Tibial Nerve** (Fig. 510) commences at the lower border of the Popliteus muscle, and passes along the back part of the leg with the posterior tibial vessels to the interval between the inner malleolus and the heel, where it divides into the *external* and *internal plantar nerves*. It lies upon the deep muscles of the leg, and is covered in the upper part by the muscles of the calf, lower down by the skin and fascia. In the upper part of its course it lies to the inner side of the posterior tibial artery, but it soon crosses that vessel, and lies to its outer side as far as the ankle. In the lower third of the leg it is placed parallel with the inner margin of the tendon Achilles.

The **branches of the posterior tibial nerve** are—muscular, plantar cutaneous, and articular.

The **muscular branches** arise either separately or by a common trunk from the upper part of the nerve. They supply the Tibialis posterior, Flexor longus digitorum, and Flexor longus hallucis muscles, the branch to the latter muscle accompanying the peroneal artery. A branch is also given to the Soleus.

The **plantar cutaneous branch** perforates the internal annular ligament and supplies the integument of the heel and inner side of the sole of the foot.

The **articular branch** is given off just above the bifurcation of the nerve and supplies the ankle-joint.

The **internal plantar nerve** (Fig. 511), the larger of the two terminal branches of the posterior tibial, accompanies the internal plantar artery along the inner side of the foot. From its origin at the inner ankle it passes beneath the Abductor hallucis, and then forward between this muscle and the Flexor brevis digitorum, divides opposite the bases of the metatarsal bones into four digital branches, and communicates with the external plantar nerve.

**Branches.**—In its course the internal plantar nerve gives off *cutaneous branches*, which pierce the plantar fascia and supply the integument of the sole of the foot; *muscular branches*, which supply the Abductor hallucis and Flexor brevis digitorum; *articular branches*, to the articulations of the tarsus and meta-
tarsus; and four digital branches. These pass between the divisions of the plantar fascia in the clefts between the toes, and are distributed in the following manner: The first supplies the inner border of the great toe, and sends a filament to the Flexor brevis hallucis muscle; the second bifurcates to supply the adjacent sides of the great and second toes, sending a filament to the First lumbrical muscle; the third digital branch supplies the adjacent sides of the second and third toes, and the Second lumbrical muscle; the fourth supplies the corresponding sides of the third and fourth toes, and receives a communicating branch from the external plantar nerve. It will be observed that the distribution of these branches is precisely similar to that of the median nerve in the hand. Each digital nerve gives off cutaneous and articular filaments, and opposite the last phalanx sends a dorsal branch, which supplies the structure round the nail, the continuation of the nerve being distributed to the ball of the toe.

The external plantar nerve, the smaller of the two, completes the nervous supply to the structures of the sole of the foot, being distributed to the little toe and one-half of the fourth, as well as to most of the deep muscles, its distribution being similar to that of the median nerve in the hand. It passes obliquely forward with the external plantar artery to the outer side of the foot, lying between the Flexor brevis digitorum and Flexor accessorius, and in the interval between the former muscle and Adductor minimi digiti divides into a superficial and a deep branch. Before its division it supplies the Flexor accessorius and Adductor minimi digiti.

The superficial branch separates into two digital nerves: one, the smaller of the two, supplies the outer side of the little toe, the Flexor brevis minimi digiti, and the two Interosseous muscles of the fourth metatarsal space; the other and larger digital branch supplies the adjoining sides of the fourth and fifth toes, and communicates with the internal plantar nerve.

The deep or muscular branch accompanies the external plantar artery into the deep part of the sole of the foot, beneath the tendons of the Flexor muscles and Adductor transversus hallucis, and supplies all the Interossei (except those in the fourth metatarsal space), the two outer Lumbricales, the Adductor obliquus hallucis, and the Adductor transversus hallucis.

The External Popliteal or Peroneal Nerve (Fig. 510), about one-half the size of the internal popliteal, descends obliquely along the outer sides of the popliteal space to the head of the fibula, close to the inner margin of the Biceps muscle. It is easily felt beneath the skin behind the head of the fibula at the inner side of the tendon of the Biceps. It passes between the tendon of the Biceps and outer head of the Gastrocnemius muscle, winds round the neck of the fibula, pierces the origin of the Peroneus longus, and divides beneath that muscle into the anterior tibial and musculo-cutaneous nerves.

The branches of the peroneal nerve, previous to its division, are articular and cutaneous.

The articular branches are three in number; two of these accompany the
superior and inferior external articular arteries to the outer side of the knee. The upper one occasionally arises from the great sciatic nerve before its bifurcation. The third (recurrent) articular nerve is given off at the point of division of the peroneal nerve; it ascends with the anterior recurrent tibial artery through the Tibialis anticus muscle to the front of the knee, which it supplies.

The cutaneous branches, two or three in number, supply the integument along the back part and outer side of the leg as far as its middle or lower part; one of these, larger than the rest, the communicans peronei, arises near the head of the fibula, crosses the external head of the Gastrocnemius to the middle of the leg, and joins with the communicans poplitei to form the external saphenous. This nerve occasionally exists as a separate branch, which is continued down as far as the heel.

The Anterior Tibial Nerve (Fig. 506) commences at the bifurcation of the peroneal nerve, between the fibula and upper part of the Peroneus longus, passes obliquely forward beneath the Extensor longus digitorum to the fore part of the interosseous membrane, and reaches the outer side of the anterior tibial artery above the middle of the leg; it then descends with the artery to the front of the ankle-joint, where it divides into an external and an internal branch. This nerve lies at first on the outer side of the anterior tibial artery, then in front of it, and again at its outer side at the ankle-joint.

The branches of the anterior tibial nerve in its course through the leg are the muscular branches to the Tibialis anticus, Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis muscles, and an articular branch to the ankle-joint.

The external or tarsal branch of the anterior tibial passes outward across the tarsus, beneath the Extensor brevis digitorum, and, having become ganglionic, like the posterior interosseous nerve at the wrist, supplies the Extensor brevis digitorum. From the ganglion are given off three minute interosseous branches which supply the tarsal joints and the metatarso-phalangeal joints of the second, third, and fourth toes. The first of these sends a filament to the second dorsal interosseous muscle.

The internal branch, the continuation of the nerve, accompanies the dorsalis pedis artery along the inner side of the dorsum of the foot, and at the first interosseous space divides into two branches, which supply the adjacent sides of the great and second toes, communicating with the internal branch of the musculo-cutaneous nerve. Before it divides it gives off an interosseous branch to the first space, which supplies the metatarso-phalangeal joint of the great toe and sends a filament to the First dorsal interosseous muscle.

The Musculo-cutaneous Nerve (Fig. 506) supplies the muscles on the fibular side of the leg and the integument of the dorsum of the foot. It passes forward between the Peronei muscles and the Extensor longus digitorum, pierces the deep fascia at the lower third of the leg on its front and outer side, and divides into two branches. This nerve in its course between the muscles gives off muscular branches to the Peroneus longus and brevis, and cutaneous filaments to the integument of the lower part of the leg.

The internal branch of the musculo-cutaneous nerve passes in front of the ankle-joint and along the dorsum of the foot, supplying the inner side of the great toe and the adjoining sides of the second and third toes. It also supplies the integument of the inner ankle and inner side of the foot, communicating with the internal saphenous nerve, and communicates with the anterior tibial nerve between the great and second toes.

The external branch, the larger, passes along the outer side of the dorsum of the foot, to be distributed to the adjoining sides of the third, fourth, and fifth toes. It also supplies the integument of the outer ankle and outer side of the foot, communicating with the short saphenous nerve. These dorsal digital nerves reach as far as the last phalanges.

The distribution of these branches of the musculo-cutaneous nerve will be
found to vary; together, they supply all the toes excepting the outer side of the little toe and the adjoining sides of the great and second toes, the former being supplied by the external saphenous, and the latter by the internal branch of the anterior tibial.

Surgical Anatomy.—The lumbar plexus passes through the Psas muscle, and, therefore in psoas abscess any or all of its branches may be irritated, causing severe pain in the part to which the irritated nerves are distributed. The genito-crural nerve is the one which is most frequently implicated. This nerve is also of importance, as it is concerned in one of the principal reflexes employed in the investigation of diseases of the spine. If the skin over the inner side of the thigh just below Poupart’s ligament, the part supplied by the crural branch of the genito-crural nerve, be gently tickled in a male child, the testicle will be noticed to be drawn upward through the action of the Cremaster muscle, supplied by the genital branch of the same nerve. The same result may sometimes be noticed in adults, and can almost always be produced by severe stimulation. This reflex, when present, shows that the portion of the cord from which the first and second lumbar nerves are derived is in a normal condition.

The anterior crural nerve is in danger of being injured in fractures of the true pelvis, since the fracture most commonly takes place through the horizontal ramus of the os pubis, at or near the point where this nerve crosses the bone. It is also liable to be injured in fractures and dislocations of the femur, and is likely to be pressed upon and its functions impaired in some tumors growing to the pelvis. Moreover, on account of its superficial position it is exposed to injury in wounds and stabs in the groin. When this nerve is paralyzed, there is loss of motion in the Iliaecus, in the Quadriiceps extensor cruris, in the Sartorius, and partial paralysis of the Pectineus. There is loss of sensation down the front and inner side of the thigh, except in that part supplied by the crural branch of the genito-crural and by the ilio-inguinal, as well as down the inner side of the leg and foot as far as the ball of the great toe.

The obturator nerve is of special surgical interest. It is rarely paralyzed alone, but occasionally in association with the anterior crural. The principal interest attached to it is in connection with its supply to the knee, pain in the knee being symptomatic of many diseases in which the trunk of this nerve or one of its branches is irritated. Thus it is well known that in the earlier stages of hip-joint disease the patient does not complain of pain in that articulation, but, on the inner side of the knee or in the knee-joint itself. Again, the same thing occurs in sacro-iliac disease. The obturator nerve is in close relationship with the sacro-iliac articulation, passing over it, and, according to some anatomists, distributing filaments to it. Again, in cancer of the sigmoid flexure, and even in cases where masses of hardened feces are impacted in this portion of the gut, pain is complained of in the knee. Finally, pain in the knee forms an important diagnostic sign in obturator hernia. The hernial protrusion as it passes out through the opening in the obturator membrane presses upon the nerve and causes pain in the parts supplied by its peripheral filaments. When the obturator nerve is paralyzed, the patient is unable to press his knees together or to cross one leg over the other, on account of paralysis of the Adductor muscles. Rotation outward of the thigh is impaired from paralysis of the Obturator externus.

The great sciatic nerve is liable to be pressed upon by various forms of pelvic tumors growing from the pelvic viscera or bones, by aneurism of some of the branches of the internal iliac artery, calculus in the bladder when of large size, accumulation of feces in the rectum, giving rise to pain along its trunk, to which the term sciatica is applied. Outside the pelvis exposure to cold, violent movements of the hip-joint, exostoses or other tumors growing from the margin of the sacro-sciatic foramen, may also give rise to the same condition. When paralyzed there is loss of motion in all the muscles below the knee, and loss of sensation in the regions supplied by it.

The sciatic nerve has been frequently cut down upon and stretched for the relief of sciatic, and also in cases of locomotor ataxy, the anæsthesia of leprosy, etc. In order to define it on the surface, a point is taken at the junction of the middle and lower third of a line stretching from the posterior superior spine of the ilium to the outer part of the tuber ischii, and a line drawn from this to the middle of the upper part of the popliteal space. The operation of stretching the sciatic nerve is performed by making an incision over the course of the nerve about the centre of the thigh. The overlying structures having been divided, the interval between the inner and outer hamstrings is to be defined, and these muscles pulled inward and outward with retractors. The nerve will be found a little to the inner side of the Biceps. It is to be separated, hooked up with the finger, and stretched by steady and continuous traction for two or three minutes. The sciatic nerve may also be stretched by what is known as the “dry” plan. The patient is laid on his back, the foot is extended, the leg flexed on the thigh, and the thigh strongly flexed on the abdomen. While the thigh is maintained in this position the leg is forcibly extended to its full extent and the foot as fully flexed on the leg.

The position of the external popliteal, close behind the tendon of the Biceps on the outer side of the ham, should be remembered in the subcutaneous division of the tendon.
The Sympathetic Nervous System consists of (1) a series of ganglia, connected together by intervening cords, extending from the base of the skull to the coccyx, one on each side of the middle line of the body, partly in front and partly on each side of the vertebral column; (2) of three great gangliated plexuses or aggregations of nerves and ganglia, situated in front of the spine in the thoracic, abdominal, and pelvic cavities respectively; (3) of smaller ganglia, situated in relation with the abdominal viscera; and (4) of numerous nerve-fibres. These latter are of two kinds: communicating, by which the ganglia communicate with each other and with the cerebro-spinal nerves; and distribitory, supplying, in general, all the internal viscera and the coats of the blood-vessels.

Each gangliated cord may be traced upward from the base of the skull into its cavity by an ascending branch, which passes through the carotid canal, forms a plexus on the internal carotid artery, and communicates with the ganglia on the first and second divisions of the fifth nerve. According to some anatomists, the two cords are joined, at their cephalic extremities, by these ascending branches communicating in a small ganglion (the ganglion of Riles), situated upon the anterior communicating artery. The ganglia of these cords are distinguished as cervical, dorsal, lumbar, and sacral, and except in the neck they correspond pretty nearly in number to the vertebrae against which they lie. They may be thus arranged:

<table>

</table>

In the neck they are situated in front of the transverse processes of the vertebrae; in the dorsal region, in front of the heads of the ribs; in the lumbar region, on the sides of the bodies of the vertebrae; and in the sacral region, in front of the sacrum. As the two cords pass into the pelvis they converge and unite together in a single ganglion (ganglion impar) placed in front of the coccyx. Each ganglion may be regarded as a distinct centre, and, in addition to its branches of distribution, possesses also branches of communication which communicate with other ganglia and with the cerebro-spinal nerves.

The branches of communication between the ganglia are composed of gray and white nerve-fibres, the latter being continuous with those fibres of the spinal nerves which pass to the ganglia.

The branches of communication between the ganglia and the cerebro-spinal nerves also consist of a white and gray portion, the former proceeding from the spinal nerve to the ganglion, the latter passing from the ganglion to the spinal nerve, so that a double interchange takes place between the two systems.

The three great gangliated plexuses are situated in front of the spine in the thoracic, abdominal, and pelvic regions, and are named, respectively, the cardiac, the solar or epigastric, and the hypogastric plexus. They consist of collections of nerves and ganglia, the nerves being derived from the gangliated cords and from the cerebro-spinal nerves. They distribute branches to the viscera.

Smaller ganglia are also found lying amidst the nerves, some of them of microscopic size, in certain viscera—as, for instance, in the heart, the stomach, and the uterus. They serve as additional centres for the origin of nerve-fibres.

The branches of distribution derived from the gangliated cords, from the prevertebral plexuses, and also from the smaller ganglia, are principally destined for the blood-vessels and thoracic and abdominal viscera, supplying the involuntary muscular fibre of the coats of the vessels and the hollow viscera, and the secreting cells, as well as the muscular coats of the vessels in the glandular viscera.

Fig. 512.—The sympathetic nerve.
CERVICAL PORTION OF THE GANGLIATED CORD. 869

In addition to these various divisions of the sympathetic, the ganglia connected with the three branches of the fifth cranial nerve are believed by some to constitute a part of the sympathetic system. These ganglia have already been described (page 799 et seq.).

THE GANGLIATED CORD.

Cervical Portion of the Gangliated Cord.

The cervical portion of the gangliated cord consists of three ganglia on each side, which are distinguished, according to their position, as the superior, middle, and inferior cervical.

The Superior Cervical Ganglion, the largest of the three, is placed opposite the second and third cervical vertebrae, and sometimes as low as the fourth or fifth. It is of a reddish-gray color, and usually fusiform in shape, sometimes broad, and occasionally constricted at intervals, so as to give rise to the opinion that it consists of the coalescence of several smaller ganglia; and it is usually believed that it is formed by the coalescence of the four ganglia, corresponding to the four upper cervical nerves. It is in relation, in front, with the sheath of the internal carotid artery and internal jugular vein; behind, it lies on the Rectus capitis anticus major muscle.

Its branches may be divided into superior, inferior, external, internal, and anterior.

The superior branch appears to be a direct prolongation of the ganglion. It is soft in texture and of a reddish color. It ascends by the side of the internal carotid artery, and, entering the carotid canal in the temporal bone, divides into two branches, which lie, one on the outer, and the other on the inner, side of that vessel.

The outer branch, the larger of the two, distributes filaments to the internal carotid artery and forms the carotid plexus.

The inner branch also distributes filaments to the internal carotid, and, continuing onward, forms the cavernous plexus.

The Carotid Plexus.

The carotid plexus is situated on the outer side of the internal carotid. Filaments from this plexus occasionally form a small gangliiform swelling on the under surface of the artery, which is called the carotid ganglion. The carotid plexus communicates with the Gasserian ganglion, with the sixth nerve, and the sphenopalatine ganglion, and distributes filaments to the wall of the carotid artery and to the dura mater (Valentin), while in the carotid canal it communicates with Jacobson’s nerve, the tympanic branch of the glossopharyngeal.

The communicating branches with the sixth nerve consist of one or two filaments which join that nerve as it lies upon the outer side of the internal carotid. Other filaments are also connected with the Gasserian ganglion. The communication with the sphenopalatine ganglion is effected by a branch, the large deep petrosal, which is given off from the plexus on the outer side of the artery, and which passes through the cartilage filling up the foramen lacerum medium, and joins the great superficial petrosal to form the Vidian nerve. The Vidian nerve then proceeds along the pterygoid or Vidian canal to the sphenopalatine ganglion. The communication with Jacobson’s nerve is effected by two branches, one of which is called the small deep petrosal nerve, and the other the long petrosal.

The Cavernous Plexus.

The cavernous plexus is situated below and internal to that part of the internal carotid which is placed by the side of the sella Tureica in the cavernous sinus, and is formed chiefly by the internal division of the ascending branch from the superior cervical ganglion. It communicates with the third, the fourth, the ophthalmic division of the fifth, and the sixth nerves, and with the ophthalmic

ganglion, and distributes filaments to the wall of the internal carotid. The branch of communication with the third nerve joins it at its point of division; the branch to the fourth nerve joins it as it lies on the outer wall of the cavernous sinus; other filaments are connected with the under surface of the trunk of the ophthalmic nerve; and a second filament of communication joins the sixth nerve.

The filament of connection with the ophthalmic ganglion arises from the anterior part of the cavernous plexus; it accompanies the nasal nerve or continues forward as a separate branch.

The terminal filaments from the carotid and cavernous plexuses are prolonged along the internal carotid, forming plexuses which entwine round the cerebral and ophthalmic arteries; along the former vessels they may be traced on to the pia mater; along the latter, into the orbit, where they accompany each of the subdivisions of the vessel, a separate plexus passing, with the arteria centralis retinae, into the interior of the eyeball. The filaments prolonged on to the anterior communicating artery form a small ganglion, the ganglion of Ribes, which serves, as mentioned above, to connect the sympathetic nerves of the right and left sides.

The inferior or descending branch of the superior cervical ganglion communicates with the middle cervical ganglion.

The external branches are numerous, and communicate with the cranial nerves and with the four upper spinal nerves. Sometimes the branch to the fourth spinal nerve may come from the cord connecting the upper and middle cervical ganglia. The branches of communication with the cranial nerves consist of delicate filaments, which pass from the superior cervical ganglion to the ganglion of the trunk of the pneumogastric and to the hypoglossal nerve. A separate filament from the cervical ganglion subdivides and joins the petrosal ganglion of the glosso-pharyngeal and the ganglion of the root of the pneumogastric in the jugular foramen.

The internal branches are three in number—the pharyngeal, laryngeal, and superior cardiac nerve. The pharyngeal branches pass inward to the side of the pharynx, where they join with branches from the glosso-pharyngeal, pneumogastric, and external laryngeal nerves to form the pharyngeal plexus. The laryngeal branches unite with the superior laryngeal nerve and its branches.

The superior cardiac nerve (nerveus superficialis cordis) arises by two or more branches from the superior cervical ganglion, and occasionally receives a filament from the cord of communication between the first and second cervical ganglia. It runs down the neck behind the common carotid artery, lying upon the Longus colli muscle, and crosses in front of the inferior thyroid artery and recurrent laryngeal nerve.

The right superior cardiac nerve, at the root of the neck, passes either in front of or behind the subclavian artery, and along the arteria innominata, to the back part of the arch of the aorta, where it joins the deep cardiac plexus. This nerve, in its course, is connected with other branches of the sympathetic: about the middle of the neck it receives filaments from the external laryngeal nerve; lower down, one or two twigs from the pneumogastric; and as it enters the thorax it is joined by a filament from the recurrent laryngeal. Filaments from this nerve communicate with the thyroid branches from the middle cervical ganglion.

The left superior cardiac nerve, in the chest, runs by the side of the left common carotid artery and in front of the arch of the aorta to the superficial cardiac plexus, but occasionally it passes behind the aorta and terminates in the deep cardiac plexus.

The anterior branches ramify upon the external carotid artery and its branches, forming round each a delicate plexus, on the nerves composing which small ganglia are occasionally found. These ganglia have been named, according to their position, intercarotid (placed at the angle of bifurcation of the common carotid), lingual, temporal, and pharyngeal. The plexuses accompanying some of these

1 The existence of this ganglion is doubted by some observers.
2 This ganglion is of the same structure as the coccygeal gland (Luschka).
arteries have important communications with other nerves. That surrounding the external carotid is connected with the branch of the facial nerve to the stylo-hyoid muscle; that surrounding the facial communicates with the submaxillary ganglion by one or two filaments; and that accompanying the middle meningeal artery sends offsets which pass to the otic ganglion and to the intumescentia ganglioformis of the facial nerve (external petrosal).

The **Middle Cervical Ganglion** (*thyroid ganglion*) is the smallest of the three cervical ganglia, and is occasionally altogether wanting. It is placed opposite the sixth cervical vertebra, usually upon, or close to, the inferior thyroid artery; hence the name, “thyroid ganglion,” assigned to it by Haller. It is probably formed by the coalescence of two ganglia corresponding to the fifth and sixth cervical nerves.

Its **superior branches** ascend to communicate with the superior cervical ganglion.

Its **inferior branches** descend to communicate with the inferior cervical ganglion.

Its **external branches** pass outward to join the fifth and sixth spinal nerves. These branches are not constantly found.

Its **internal branches** are the thyroid and the middle cardiac nerve.

The **thyroid branches** are small filaments which accompany the inferior thyroid artery to the thyroid gland; they communicate, on the artery, with the superior cardiac nerve, and, in the gland, with branches from the recurrent and external laryngeal nerves.

The **middle cardiac nerve** (*nervus cardiacus magnus*), the largest of the three cardiac nerves, arises from the middle cervical ganglion or from the cord between the middle and inferior ganglia. On the right side it descends behind the common carotid artery, and at the root of the neck passes either in front of or behind the subclavian artery; it then descends on the trachea, receives a few filaments from the recurrent laryngeal nerve, and joins the deep cardiac plexus. In the neck it communicates with the superior cardiac and recurrent laryngeal nerves. On the left side the middle cardiac nerve enters the chest between the left carotid and subclavian arteries, and joins the left side of the deep cardiac plexus.

The **Inferior Cervical Ganglion** is situated between the base of the transverse process of the last cervical vertebra and the neck of the first rib on the inner side of the superior intercostal artery. Its form is irregular; it is larger in size than the preceding, and frequently joined with the first thoracic ganglion. It is probably formed by the coalescence of two ganglia which correspond to the two last cervical nerves.

Its **superior branches** communicate with the middle cervical ganglion.

Its **inferior branches** descend, some in front of, others behind, the subclavian artery, to join the first thoracic ganglion.

Its **internal branch** is the inferior cardiac nerve.

The **inferior cardiac nerve** (*nervus cardiacus minor*) arises from the inferior cervical or first thoracic ganglion. It passes down behind the subclavian artery and along the front of the trachea to join the deep cardiac plexus. It communicates freely behind the subclavian artery with the recurrent laryngeal and middle cardiac nerves.

The **external branches** consist of several filaments, some of which communicate with the seventh and eighth spinal nerves; others accompany the vertebral artery along the vertebral canal, forming a plexus round the vessel, supplying it with filaments, and communicating with the cervical spinal nerves as high as the fourth.

**Thoracic Portion of the Gangliated Cord.**

The thoracic portion of the gangliated cord consists of a series of ganglia which usually correspond in number to that of the vertebrae, but, from the occasional coalescence of two, their number is uncertain. These ganglia are placed on each side of the spine, resting against the heads of the ribs and covered by the
pleura costalis; the last two are, however, anterior to the rest, being placed on the side of the bodies of the eleventh and twelfth dorsal vertebrae. The ganglia are small in size and of a grayish color. The first, larger than the rest, is of an elongated form and frequently blended with the last cervical. They are connected together by cord-like prolongations from their substance.

The *external branches* from each ganglion, usually two in number, communicate with each of the dorsal spinal nerves.

The *internal branches from the six upper ganglia* are very small; they supply filaments to the thoracic aorta and its branches, besides small branches to the bodies of the vertebrae and their ligaments. Branches from the third and fourth, and sometimes also from the first and second ganglia, form part of the posterior pulmonary plexus.

The *internal branches from the six lower ganglia* are large and white in color; they distribute filaments to the aorta and unite to form the three splanchnic nerves. These are named the *great*, the *lesser*, and the *smallest or renal splanchnic*.

The *great splanchnic nerve* is of a white color, firm in texture, and bears a marked contrast to the ganglionic nerves. It is formed by branches from the thoracic ganglia between the sixth and tenth, receiving filaments (according to Dr. Beck) from all the thoracic ganglia above the sixth. These roots unite to form a large round cord of considerable size. It descends obliquely inward in front of the bodies of the vertebrae along the posterior mediastinum, perforates the crus of the Diaphragm, and terminates in the semilunar ganglion, distributing filaments to the renal and suprarenal plexus.

The *lesser splanchnic nerve* is formed by filaments from the tenth and eleventh ganglia and from the cord between them. It pierces the Diaphragm with the preceding nerve and joins the celiac plexus. It communicates in the chest with the great splanchnic nerve, and occasionally sends filaments to the renal plexus.

The *smallest, or renal, splanchnic nerve* arises from the last ganglion, and, piercing the Diaphragm, terminates in the renal plexus and lower part of the celiac plexus. It occasionally communicates with the preceding nerve.

A striking analogy appears to exist between the splanchnic and the cardiac nerves. The cardiac nerves are three in number; they arise from the three cervical ganglia, and are distributed to a large and important organ in the thoracic cavity. The splanchnic nerves, also three in number, are connected probably with all the dorsal ganglia, and are distributed to important organs in the abdominal cavity.

The Lumbar Portion of the Gangliated Cord.

The lumbar portion of the gangliated cord is situated in front of the vertebral column along the inner margin of the Psoas muscle. It consists usually of four ganglia, connected together by interganglionic cords. The ganglia are of small size, of a grayish color, shaped like a barleycorn, and placed much nearer the median line than the thoracic ganglia.

The *superior and inferior branches of the lumbar ganglia* serve as communicating branches between the chain of ganglia in this region. They are usually single and of a white color.

The *external branches* communicate with the lumbar spinal nerves. From the situation of the lumbar ganglia these branches are longer than in other regions. They are usually two in number from each ganglion, but their connection with the spinal nerves is not so uniform as in other regions. They accompany the lumbar arteries around the sides of the bodies of the vertebrae, passing beneath the fibrous arches from which some of the fibres of the Psoas muscle arise.

Of the *internal branches*, some pass inward, in front of the aorta, and help to form the aortic plexus. Other branches descend in front of the common iliac arteries, and join over the promontory of the sacrum, helping to form the hypogastric plexus. Numerous delicate filaments are also distributed to the bodies of the vertebrae and the ligaments connecting them.
Pelvic Portion of the Gangliated Cord.

The pelvic portion of the gangliated cord is situated in front of the sacrum along the inner side of the anterior sacral foramina. It consists of four or five small ganglia on each side, connected together by interganglionic cords. Below, these cords converge and unite on the front of the coccyx by means of a small ganglion (the coccygeal ganglion or ganglion impar).

The superior and inferior branches are the cords of communication between the ganglia above and below.

The external branches, exceedingly short, communicate with the sacral nerves. They are two in number from each ganglion. The coccygeal nerve communicates either with the last sacral or coccygeal ganglion.

The internal branches communicate, on the front of the sacrum, with the corresponding branches from the opposite side; some, from the first two ganglia, pass to join the pelvic plexus, and others form a plexus which accompanies the middle sacral artery and sends filaments to the coccygeal gland.

THE GREAT PLEXUSES OF THE SYMPATHETIC.

The great plexuses of the sympathetic are the large aggregations of nerves and ganglia, above alluded to, situated in the thoracic, abdominal, and pelvic cavities respectively. From them are derived the branches which supply the viscera.

The Cardiac Plexus.

The cardiac plexus is situated at the base of the heart, and is divided into a superficial part, which lies in the concavity of the arch of the aorta, and a deep part, which lies between the trachea and aorta.

The great or deep cardiac plexus (plexus magnus profundus, Scarpa) is situated in front of the trachea at its bifurcation, above the point of division of the pulmonary artery and behind the arch of the aorta. It is formed by the cardiac nerves derived from the cervical ganglia of the sympathetic and the cardiac branches of the recurrent laryngeal and pneumogastric. The only cardiac nerves which do not enter into the formation of this plexus are the left superior cardiac nerve and the left inferior cervical cardiac branch from the pneumogastric.

The branches from the right side of this plexus pass, some in front of, and others behind, the right pulmonary artery; the former, the more numerous, transmit a few filaments to the anterior pulmonary plexus, and are then continued onward to form part of the anterior coronary plexus; those behind the pulmonary artery distribute a few filaments to the right auricle, and are then continued onward to form part of the posterior coronary plexus.

The branches from the left side of the deep cardiac plexus distribute a few filaments to the superficial cardiac plexus, to the left auricle of the heart, and to the anterior pulmonary plexus, and then pass on to form the greater part of the posterior coronary plexus.

The superficial (anterior) cardiac plexus lies beneath the arch of the aorta, in front of the right pulmonary artery. It is formed by the left superior cardiac nerve, the left (and occasionally the right) inferior cervical cardiac branches of the pneumogastric, and filaments from the deep cardiac plexus. A small ganglion (cardiac ganglion of Wrisberg) is occasionally found connected with these nerves at their point of junction. This ganglion, when present, is situated immediately beneath the arch of the aorta, on the right side of the ductus arteriosus. The superficial cardiac plexus forms the chief part of the anterior coronary plexus, and several filaments pass along the pulmonary artery to the left anterior pulmonary plexus.

The posterior coronary plexus is chiefly formed by filaments prolonged from the left side of the deep cardiac plexus, and by a few from the right side. It surrounds the branches of the coronary artery at the back of the heart, and its
THE EPIGASTRIC OR SOLAR PLEXUS.

filaments are distributed with those vessels to the muscular substance of the ventricles.

The anterior coronary plexus is formed chiefly from the superficial cardiac plexus, but receives filaments from the deep cardiac plexus. Passing forward between the aorta and pulmonary artery, it accompanies the left coronary artery on the anterior surface of the heart.

Valentin has described nervous filaments ramifying under the endocardium; and Remak has found, in several mammalia, numerous small ganglia on the cardiac nerves, both on the surface of the heart and in its muscular substance.

The Epigastric or Solar Plexus (Figs. 512, 514).

The Epigastric or Solar plexus supplies all the visceras in the abdominal cavity. It consists of a great network of nerves and ganglia, situated behind the stomach and in front of the aorta and crura of the Diaphragm. It surrounds the coeliac axis and root of the superior mesenteric artery, extending downward as low as the pancreas and outward to the suprarenal capsules. This plexus, and the ganglia connected with it, receive the great splanchic nerve of both sides, and some filaments from the right pneumogastric. It distributes filaments which accompany, under the name of plexuses, all the branches from the front of the abdominal aorta.

The semilunar ganglia of the solar plexus, two in number, one on each side, are the largest ganglia in the body. They are large irregular gangliform masses formed by the aggregation of smaller ganglia, having interspaces between them. They are situated in front of the crura of the Diaphragm, close to the suprarenal capsules: the one on the right side lies beneath the inferior vena cava; the upper part of each ganglion is joined by the greater splanchnic nerve, and to the inner side of each the branches of the solar plexus are connected.

From the epigastric or solar plexus are derived the following:

The phrenic plexus accompanies the phrenic artery to the Diaphragm, which it supplies, some filaments passing to the suprarenal capsule. It arises from the upper part of the semilunar ganglion, and is larger on the right than on the left side. It receives one or two branches from the phrenic nerve. In connection with this plexus, on the right side, at its point of junction with the phrenic nerve, is a small ganglion (ganglion diaphragmaticum). This ganglion is placed on the under surface of the Diaphragm, near the suprarenal capsule. Its branches are distributed to the inferior vena cava, suprarenal capsule, and hepatic plexus. There is no ganglion on the left side.

The suprarenal plexus is formed by branches from the solar plexus, from the semilunar ganglion, and from the phrenic and great splanchnic nerves, a ganglion being formed at the point of junction of the latter nerve. It supplies the suprarenal capsule. The branches of this plexus are remarkable for their large size in comparison with the size of the organ they supply.

The renal plexus is formed by filaments from the solar plexus, the outer part of the semilunar ganglion, and the aortic plexus. It is also joined by filaments from the lesser and smallest splanchnic nerves. The nerves from these sources, fifteen or twenty in number, have numerous ganglia developed upon them. They accompany the branches of the renal artery into the kidney, some filaments on the right side being distributed to the inferior vena cava, and others to the spermatic plexus on both sides.

The spermatic plexus is derived from the renal plexus, receiving branches from the aortic plexus. It accompanies the spermatic vessels to the testes.
In the female the ovarian plexus is distributed to the ovaries and fundus of the uterus.

The coeliac plexus, of large size, is a direct continuation from the solar plexus: it surrounds the coeliac axis and subdivides into the gastric, hepatic, and splenic
plexuses. It receives branches from the lesser splanchnic nerves, and, on the left side, a filament from the right pneumogastric.

The **gastric or coronary plexus** accompanies the gastric artery along the lesser curvature of the stomach, and joins with branches from the left pneumogastric nerve. It is distributed to the stomach.

The **hepatic plexus**, the largest offset from the cœliac plexus, receives filaments from the left pneumogastric and right phrenic nerves. It accompanies the hepatic artery, ramifying in the substance of the liver upon its branches and upon those of the vena portae.

Branches from this plexus accompany all the divisions of the hepatic artery. Thus there is a **pyloric plexus** accompanying the pyloric branch of the hepatic, which joins with the gastric plexus and pneumogastric nerves. There is also a **gastro-duodenal plexus**, which subdivides into the pancreatico-duodenal plexus, which accompanies the pancreatico-duodenal artery, to supply the pancreas and duodenum, joining with branches from the mesentric plexus; and a **gastro-epiploic plexus**, which accompanies the right gastro-epiploic artery along the greater curvature of the stomach and anastomoses with branches from the splenic plexus.

A **cystic plexus**, which supplies the gall-bladder, also arises from the hepatic plexus near the liver.

The **splenic plexus** is formed by branches from the cœliac plexus, the left semilunar ganglia, and from the right pneumogastric nerve. It accompanies the splenic artery and its branches to the substance of the spleen, giving off, in its course, filaments to the pancreas (**pancreatic plexus**) and the left gastro-epiploic **plexus**, which accompanies the gastro-epiploica sinistra artery along the convex border of the stomach.

The **superior mesentric plexus** is a continuation of the lower part of the great solar plexus, receiving a branch from the junction of the right pneumogastric nerve with the cœliac plexus. It surrounds the superior mesentric artery, which it accompanies into the mesentry, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery—viz. pancreatic branches to the pancreas; intestinal branches, which supply the whole of the small intestine; and ileo-colic, right colic, and middle colic branches, which supply the corresponding parts of the great intestine. The nerves composing this plexus are white in color and firm in texture, and have numerous ganglia developed upon them near their origin.

The **aortic plexus** is formed by branches derived, on each side, from the solar plexus and the semilunar ganglia, receiving filaments from some of the lumbar ganglia. It is situated upon the sides and front of the aorta, between the origins of the superior and inferior mesentric arteries. From this plexus arise part of the spermatic, the inferior mesentric, and the hypogastric plexuses; and it distributes filaments to the inferior vena cava.

The **inferior mesentric plexus** is derived chiefly from the left side of the aortic plexus. It surrounds the inferior mesentric artery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery—viz. the left colic and sigmoid plexuses, which supply the descending and sigmoid flexure of the colon; and the superior haemorrhoidal plexus, which supplies the upper part of the rectum and joins in the pelvis with branches from the pelvic plexus.

The Hypogastric Plexus.

The **Hypogastric Plexus** supplies the viscera of the pelvic cavity. It is situated in front of the promontory of the sacrum, between the two common iliac arteries, and is formed by the union of numerous filaments, which descend on each side from the aortic plexus and from the lumbar ganglia. This plexus contains no ganglia, and bifurcates, below, into two lateral portions, which form the pelvic plexuses.
The Pelvic Plexus.

The Pelvic Plexus (sometimes called inferior hypogastric) supplies the viscera of the pelvic cavity, is situated at the side of the rectum and bladder in the male, and at the side of the rectum, vagina, and bladder in the female. It is formed by a continuation of the hypogastric plexus, by branches from the second, third, and fourth sacral nerves, and by a few filaments from the first two sacral ganglia. At the point of junction of these nerves small ganglia are found. From this plexus numerous branches are distributed to all the viscera of the pelvis. They accompany the branches of the internal iliac artery.

The inferior haemorrhoidal plexus arises from the back part of the pelvic plexus. It supplies the rectum, joining with branches of the superior haemor-rhoidal plexus.

The vesical plexus arises from the fore part of the pelvic plexus. The nerves composing it are numerous, and contain a large proportion of spinal nerve-fibres. They accompany the vesical arteries, and are distributed at the side and base of the bladder. Numerous filaments also pass to the vesicule seminales and vas deferens; those accompanying the vas deferens join, on the spermatic cord, with branches from the spermatic plexus.

The prostatic plexus is continued from the lower part of the pelvic plexus. The nerves composing it are of large size. They are distributed to the prostate gland, vesicule seminales, and erectile structure of the penis. The nerves supplying the erectile structure of the penis consist of two sets, the small and large cavernous nerves. They are slender filaments, which arise from the fore part of the prostatic plexus, and, after joining with branches from the internal pudic nerve, pass forward beneath the pubic arch.

The small cavernous nerves perforate the fibrous covering of the penis near its roots.

The large cavernous nerve passes forward along the dorsum of the penis, joins with the dorsal branch of the pudic nerve, and is distributed to the corpus cavernosum and spongiosum.

The vaginal plexus arises from the lower part of the pelvic plexus. It is lost on the walls of the vagina, being distributed to the erectile tissue at its anterior part and to the mucous membrane. The nerves composing this plexus contain, like the vesical, a large proportion of spinal nerve-fibres.

The uterine plexus arises from the upper part of the pelvic plexus above the point where the branches from the sacral nerves join the plexus. Its branches accompany the uterine arteries to the side of the organ between the layers of the broad ligament, and are distributed to the cervix and lower part of the body of the uterus, penetrating its substance.

Other filaments pass separately to the body of the uterus and Fallopian tube. Branches from the plexus accompany the uterine arteries into the substance of the uterus. Upon these filaments ganglionic enlargements are found.
THE ORGANS OF SENSE.

The Organs of the Senses are five in number—viz. those of Touch, of Taste, of Smell, of Hearing, and of Sight. The skin, which is the principal seat of the sense of touch, has been described in the chapter on General Anatomy.

THE TONGUE.

The Tongue is the organ of the special sense of taste. It is situated in the floor of the mouth, in the interval between the two lateral portions of the body of the lower jaw.

Its base or root is directed backward, and connected with the os hyoides by the Hyo-glossi and Genio-hyo-glossi muscles and the hyo-glossal membrane; with the epiglottis by three folds of mucous membrane which form the glosso-epiglottic ligaments; with the soft palate by means of the anterior pillars of the fauces; and with the pharynx by the Superior constrictor and the mucous membrane. Its apex or tip, thin and narrow, is directed forward against the inner surface of the lower incisor teeth. The under surface of the tongue is connected with the lower jaw by the Genio-hyo-glossi muscles; from its sides the mucous membrane is reflected to the inner surface of the gums; and in front a distinct fold of that membrane, the frenum linguae, is formed beneath its under surface.

The tip of the tongue, part of the under surface, its sides and dorsum, are free.

The dorsum of the tongue is convex, marked along the middle line by a raphe, which divides it into symmetrical halves; this raphe terminates behind, about an inch from the base of the organ, in a depression, the foramen cecum. The anterior two-thirds of this surface are rough and covered with papillae; the posterior third is smoother, and covered by the projecting orifices of numerous muciparous glands.

Structure of the Tongue.—The tongue is partly invested by mucous membrane and a submucous fibrous layer. It consists of symmetrical halves, separated from each other, in the middle line, by a fibrous septum. Each half is composed of muscular fibres arranged in various directions, containing much interposed fat, and supplied by vessels and nerves.

The mucous membrane invests the entire extent of the free surface of the tongue. On the dorsum it is thicker behind than in front, and is continuous with the sheath of the muscles attached to it, through the submucous fibrous layer. On the under surface of the organ it can be traced on each side of the frenum through the ducts of the submaxillary and the sublingual glands. As it passes over the borders of the organ it gradually assumes its papillary character.

The structure of the mucous membrane of the tongue differs in different parts. That covering the under surface of the organ is thin, smooth, and identical in
structure with that lining the rest of the oral cavity. The mucous membrane on
the anterior part of the dorsum of the tongue is thin and intimately adherent to
the muscular tissue, whilst that at the root is much thicker and looser. It consists

of a layer of connective tissue, the corium or mucosa, supporting numerous papillæ
and covered, as well as the papillæ, with epithelium.

The epithelium is of the scaly variety, like that of the epidermis. It covers the
free surface of the tongue, as may be easily demonstrated by maceration or boiling,
when it can be easily detached entire: it is much thinner than on the skin: the
intervals between the large papillæ are not filled up by it, but each papilla has
a separate investment from root to summit. The deepest cells may sometimes
be detached as a separate layer, corresponding to the rete mucosum, but they
never contain coloring matter.

The corium consists of a dense feltwork of fibrous connective tissue, with
numerous elastic fibres, firmly connected with the fibrous tissue forming the septa
between the muscular bundles of the tongue. It contains the ramifications of the
numerous vessels and nerves from which the papillæ are supplied, large plexuses
of lymphatic vessels, and the glands of the tongue.

The Papillæ of the Tongue.—These are papillary projections of the corium.
They are thickly distributed over the anterior two-thirds of its upper surface, giving
to it its characteristic roughness. The varieties of papillæ met with are—the
papillæ maxima (circumvallatae), papillæ mediaæ (fungiformes), papillæ minimaæ
(conica or filiformes), and papillæ simplices.

The papillæ maxima (circumvallatae) are of large size, and vary from eight to
twelve in number. They are situated at the back part of the dorsum of the tongue,
near its base, forming a row on each side, which, running backward and inward,
meet in the middle line, like the two lines of the letter V inverted. Each papilla
consists of a projection of mucous membrane from \( \frac{1}{10} \) to \( \frac{1}{12} \) inch wide,
attached to the bottom of a cup-shaped depression of the mucous membrane; the
papilla is in shape like a truncated cone, the smaller end being directed down-
ward and attached to the tongue, the broader part or base projecting on the sur-
face and being studded with numerous small secondary papillæ, which, however,
are covered by a smooth layer of the epithelium. The cup-shaped depression forms
a kind of fossa round the papilla, having a circular margin of about the
same elevation covered with smaller papillæ. At the point of junction of the two
rows of papillæ is the deep depression, the foramen cecum, mentioned above.

The papillæ mediaæ (fungiformes), more numerous than the preceding, are
scattered irregularly and sparingly over the dorsum of the tongue, but are found
chiefly at its sides and apex. They are easily recognized among the other
papillæ, by their large size, rounded eminences, and deep-red color. They are
narrow at their attachment to the tongue, but broad and rounded at their free
extremities, and covered with secondary papillae. Their epithelial investment is very thin.

The papille minima (conicæ or filiformes) cover the anterior two-thirds of the dorsum of the tongue. They are very minute, more or less conical or filiform in shape, and arranged in lines corresponding in direction with the two rows of the papille circumvallatae, excepting at the apex of the organ, where their direction is transverse. They have projecting from their apices numerous filiform processes or secondary papillæ, which are of a whitish tint, owing to the thickness and density of the epithelium of which they are composed, and which has here undergone a peculiar modification, the cells having become cornified and elongated into dense, imbricated, brush-like processes. They contain also a number of elastic fibres, which render them firmer and more elastic than the papillæ of mucous membrane generally.

Simple papillæ, similar to those of the skin, cover the whole of the mucous membrane of the tongue, as well as the larger papillæ. They consist of closely-set, microscopic elevations of the corium, containing a capillary loop, covered by a layer of epithelium.

Structure of the Papillæ.—The papillæ apparently resemble in structure those of the cutis, consisting of a cone-shaped projection of connective tissue, covered with a thick layer of squamous epithelium, and contain one or more capillary loops, amongst which nerves are distributed in great abundance. If the epithelium is removed, it will be found that they are not simple elevations like the papillæ of the skin, for the surface of each is studded with minute conical processes of the mucous membrane, which form secondary papillæ (Todd and Bowman). In the papillæ circumvallatae the nerves are numerous and of large size; in the papillæ fungiformes they are also numerous, and terminate in a plexiform network, from which brush-like branches proceed; in the papillæ filiformes their mode of termination is uncertain. Buried in the epidermis of the papillæ circumvallatae, and in some of the fungiformes, certain peculiar bodies called taste-goblets have been described. They are flask-like in shape, their broad base resting on the corium, and their neck opening by an orifice between the cells of the epithelium. They are formed by two kinds of cells: the external (cortical) are arranged in several layers; they are long and flattened, with tapering ends, and in contact by their edges, the tapering extremities extending from the base to the apex of the organ. Their apical ends bound the orifice (gustatory pore) just mentioned. They thus enclose the central cells (gustatory cells), which are spindle-shaped and have a large spherical nucleus about the middle of the cell. Both extremities of a gustatory cell are filamentous; the inner process is described (denied by G. Retzius) as continuous with the terminal fibril of a nerve (glosso-pharyngeal), while the outer one projects as an extremely fine hair through the orifice of the taste-goblet.

1 These bodies are also found in considerable numbers at the side of the base of the tongue, just in front of the anterior pillars of the fauces.

Glands of the Tongue.—The tongue is provided with mucous and serous glands and lymphoid follicles.

The mucous glands are similar in structure to the labial and buccal glands. They are found all over the surface of the mucous membrane of the tongue, especially at the back part, behind the circumvallate papillae, but also at the apex and marginal parts. In connection with these glands a special one has been described by Blandin and Nuhn. It is situated near the apex of the tongue on either side of the frenum, and is covered over by a fasciculus of muscular fibre derived from the Stylo-glossus and Inferior lingualis. It is from half an inch to nearly an inch long and about the third of an inch broad. It has from four to six ducts, which open on the under surface of the apex.

The serous glands occur only at the back of the tongue in the neighborhood of the taste-goblets, their ducts opening for the most part into the fosse of the circumvallate papillae. These glands are racemose, the duct branching into several minute ducts, which terminate in alveoli lined by a single layer of more or less columnar epithelium. Their secretion is of a watery nature, and probably assists in the distribution of the substance to be tasted over the taste-area (Ebner).

The Lymphoid Follicles.—The lymphoid tissue is situated, for the most part at the back of the tongue, between the epiglottis and the circumvallate papillae, and is collected at numerous points into distinct masses known as lymphoid follicles. Here and there in this situation are depressions in the mucous membrane, surrounded by nodules of lymphoid tissue, similar to the structure found in the tonsil: into them open some of the ducts of the mucous glands.

The fibrous septum consists of a vertical layer of fibrous tissue, extending throughout the entire length of the middle line of the tongue, from the base to the apex, though not quite reaching the dorsum. It is thicker behind than in front, and occasionally contains a small fibro-cartilage about a quarter of an inch in length. It is well displayed by making a vertical section across the organ.

The Hyo-glossal membrane is a strong fibrous lamina which connects the under surface of the base of the tongue to the body of the hyoid bone. This membrane receives, in front, some of the fibres of the Genio-hyo-glossi.

Vessels of the Tongue.—The arteries of the tongue are derived from the lingual, the facial, and ascending pharyngeal. The veins of the tongue accompany the arteries.

Muscles of the Tongue.—The muscular fibres of the tongue run in various directions. These fibres are divided into two sets, Extrinsic and Intrinsic.

The Extrinsic muscles of the tongue are those which have their origin external to it, and only their terminal fibres contained in the substance of the organ. They are the Stylo-glossus, the Hyo-glossus, the Palato-glossus, the Genio-hyo-glossus, and part of the Superior constrictor of the pharynx (Pharyngo-glossus).

The Intrinsic muscles are those which are contained entirely within the tongue and form the greater part of its substance. Both sets have been already described (page 415).

The lymphatic vessels from the tongue pass to one or two small glands situated
on the Hyo-glossus muscle in the submaxillary region, and from thence to the deep glands of the neck.

The nerves of the tongue are four in number in each half: the lingual branch of the fifth, which is distributed to the papillae at the fore part and sides of the tongue; the lingual branch of the glosso-pharyngeal, which is distributed to the mucous membrane at the base and side of the tongue and to the papillae circum-

![Diagram of tongue and surrounding anatomy]

**Fig. 520.**—Under surface of the tongue, showing the distribution of nerves to this organ. (From a preparation in the Museum of the Royal College of Surgeons.)

vallate; the hypoglossal nerve, which is distributed to the muscular substance of the tongue; and the chorda tympani to the Lingualis muscle. Sympathetic filaments also pass to the tongue from the nervi molles on the lingual and other arteries supplying it. The glosso-pharyngeal branch is the special nerve of the sense of taste, the lingual (gustatory) is the nerve of common sensation, and the hypoglossal is the motor nerve of the tongue, except for the Inferior lingualis, which is supplied by the chorda tympani.

**Surgical Anatomy.**—The diseases to which the tongue is liable are numerous, and its surgical anatomy of importance, since any or all the structures of which it is composed—muscles, connective tissue, mucous membrane, glands, vessels, nerves, and lymphatics—may be the seat of morbid changes. It is not often the seat of congenital defects, though a few cases of vertical cleft have been recorded, and it is occasionally, though much more rarely than is commonly supposed, the seat of "tongue-tie," from shortness of the frenum. (See page 554.)

There is, however, one condition which must be regarded as congenital, though it does not sometimes evidence itself until a year or two after birth, which is not uncommon. This is an enlargement of the tongue which is due primarily to a dilatation of the lymph-channels and a greatly increased development of the lymphatic tissue throughout the tongue. This is often
aggravated by inflammatory changes induced by injury or exposure, and the tongue may assume enormous dimensions and hang out of the mouth, giving the child an imbecile expression. The treatment consists in excising a V-shaped portion and bringing the cut surfaces together with deeply-placed silver sutures. Compression has been resorted to in some cases and with success, but it is difficult to apply. Acute inflammation of the tongue, which may be caused by injury and the introduction of some septic or irritating matter, is attended by great swelling from infiltration of its connective tissue, which is in considerable quantity. This renders the patient incapable of swallowing or speaking, and may seriously impede respiration. It may run on to suppuration and the formation of an acute abscess. Chronic abscess, which has been mistaken for cancer, may also occur in the substance of the tongue.

The mucous membrane of the tongue may become chronically inflamed, and presents different appearances in different stages of the disease, to which the terms leueoplaenia, psoriasis, and ichthyosis have been given.

The tongue, being very vascular, is often the seat of nevoid growths, and these have a tendency to grow rapidly.

The tongue is frequently the seat of ulceration, which may arise from many causes, as from the irritation of jagged teeth, dyspepsia, tubercle, syphilis, and cancer. Of these the cancerous ulcer is the most important, and probably also the most common. The variety is the squamous epithelioma, which soon develops into an ulcer with an indurated base. It produces great pain, which speedily extends to all parts supplied with sensation by the fifth nerve, especially to the region of the ear. The pain in these cases is conducted to the ear and temporal region by the lingual nerve, and from it to the other branches of the inferior maxillary nerve, especially the auriculo-temporal. Possibly pain in the ear itself may be due to impaction of the fibres of the glosso-pharyngeal nerve, which by its tympanic branch is conducted to the tympanic plexus.

Cancer of the tongue may necessitate removal of a part or the whole of the organ, and many different methods have been adopted for its excision. It may be removed from the mouth by the érasceur or the scissors. Probably the better method is by the scissors, usually known as Whitehead's method. The mouth is widely opened with a gag, the tongue transfixed with a stout silk ligature, by which to hold and make traction on it and the reflection of mucous membrane from the tongue to the jaw, and the insertion of the Genio-hyo-glossus first divided with a pair of curved blunt scissors. The Palato-glossus is also divided. The tongue can now be pulled well out of the mouth. The base of the tongue is cut through by a series of short snips, each bleeding vessel being dealt with as soon as divided, until the situation of the ranine artery is reached. The remaining undivided portion of tissue is to be seized with a pair of Wells's forceps, the tongue removed, and the vessel secured. In the event of the ranine artery being accidentally injured haemorrhage can be at once controlled by passing two fingers over the dorsum of the tongue as far as the epiglottis and dragging the root of the tongue forcibly forward.

In cases where the disease is confined to one side of the tongue this operation may be modified by splitting the tongue down the centre and removing only the affected half. In cases where the submaxillary glands are involved Kocher's operation should be performed. He removes the tongue from the neck, having performed a preliminary tracheotomy, by an incision from near the lobule of the ear, down the anterior border of the Sterno-mastoid to the level of the great cornu of the hyoid bone, then forward to the body of the hyoid bone, and upward to near the symphysis of the jaw. The lingual artery is now secured, and by a careful dissection the submaxillary lymphatic glands and the tongue removed. Regnoli advocated the removal of the tongue by a semilunar incision in the submaxillary triangle along the line of the lower jaw, and a vertical incision from the centre of the semilunar one backward to the hyoid bone. Care must be taken not to carry the first incision too far backward, so as to wound the facial arteries. The tongue is thus reached through the floor of the mouth, pulled out through the external incision, and removed with the érasceur or knife. The great objection to this operation is that all the muscles which raise the hyoid bone and larynx are divided, and that therefore the movements of deglutition and respiration are interfered with.

Finally, where both sides of the floor of the mouth are involved in the disease, or where very free access is required on account of the extension backward of the disease to the pillars of the fauces and the tonsil, or where the lower jaw is involved, the operation recommended by Syme must be performed. This is done by an incision through the central line of the lip, across the chin, and down as far as the hyoid bone. The lower jaw is sawn through at the symphysis, and the two halves of the bone forcibly separated from each other. The mucous membrane is separated from the bone, and the Genio-hyo-glossus detached from the bone, and the Hyo-glossus divided. The tongue is then drawn forward and removed close to its attachment to the hyoid bone. Any glands which are enlarged can be removed, and if the bone is implicated in the disease, it can also be removed by freeing it from the soft parts externally and internally, and making a second section with the saw beyond the diseased part.

Formerly many surgeons before removing the tongue performed a preliminary tracheotomy: (1) to prevent blood entering the air-passages; and (2) to allow the patient to breathe through the tube and not inspire air which had passed over a sloughy wound, and which was loaded with septic organisms and likely to induce septic pneumonia. By the judicious use of iodoform this secondary evil may be obviated, and the preliminary tracheotomy is now usually dispensed with.
THE NOSE.

The nose is the special organ of the sense of smell: by means of the peculiar properties of its nerves it protects the lungs from the inhalation of deleterious gases and assists the organ of taste in discriminating the properties of food.

The organ of smell consists of two parts—one external, the nose; the other internal, the nasal fossæ.

The nose is the more anterior and prominent part of the organ of smell. It is of a triangular form, directed vertically downward, and projects from the centre of the face immediately above the upper lip. Its summit or root is connected directly with the forehead. Its inferior part, the base of the nose, presents two elliptical orifices, the nostrils, separated from each other by an antero-posterior septum, the columna. The margins of these orifices are provided with a number of stiff hairs, or vibrissæ, which arrest the passage of foreign substances carried with the current of air intended for respiration. The lateral surfaces of the nose form, by their union, the dorsum, the direction of which varies considerably in different individuals. The dorsum terminates below in a rounded eminence, the lobe of the nose.

The nose is composed of a framework of bones and cartilages, the latter being slightly acted upon by certain muscles. It is covered externally by the integument, internally by mucous membrane, and supplied with vessels and nerves.

The bony framework occupies the upper part of the organ: it consists of the nasal bones and the nasal processes of the superior maxillary.

The cartilaginous framework consists of five pieces, the two upper and the two lower lateral cartilages and the cartilage of the septum.

The upper lateral cartilages are situated below the free margin of the nasal bones; each cartilage is flattened and triangular in shape. Its anterior margin is thicker than the posterior, and connected with the fibro-cartilage of the septum. Its posterior margin is attached to the nasal process of the superior maxillary and nasal bones. Its inferior margin is connected by fibrous tissue with the lower lateral cartilage; one surface is turned outward, the other inward toward the nasal cavity.

The lower lateral cartilages are two thin, flexible plates situated immediately below the preceding, and bent upon themselves in such a manner as to form the inner and outer walls of each orifice of the nostril. The portion which forms the inner wall, thicker than the rest, is loosely connected with the same part of the opposite cartilage, and forms a small part of the columna. Its inferior border, free, rounded, and projecting, forms, with the thickened integument and subjacent...
cent tissue and the corresponding parts of the opposite side, the tip of the nose. The part which forms the outer wall is curved to correspond with the ala of the nose; it is oval and flattened, narrow behind, where it is connected with the nasal process of the superior maxilla by a tough fibrous membrane, in which are found three or four small cartilaginous plates (sesamoid cartilages), cartilagines minores. Above, it is connected to the upper lateral cartilage and front part of the cartilage of the septum; below, it is separated from the margin of the nostril by dense cellular tissue; and in front, it forms, with its fellow, the lobe of the nose.

The cartilage of the septum is somewhat quadrilateral in form, thicker at its margins than at its centre, and completes the separation between the nasal fossae in front. Its anterior margin, thickest above, is connected from above downward with the nasal bones, the anterior margin of the two upper lateral cartilages, and the inner portion of the two lower lateral cartilages. Its posterior margin is connected with the perpendicular lamella of the ethmoid, its inferior margin with the vomer and the palate processes of the superior maxillary bones.

These various cartilages are connected to each other and to the bones by a tough fibrous membrane, which allows the utmost facility of movement between them.

The muscles of the nose are situated immediately beneath the integument: they are (on each side) the Pyramidalis nasi, the Levator labii superioris alaeque nasi, the Dilatator naris, anterior and posterior, the Compressor nasi, the Compressors narium minor, and the Depressor alae nasi. They have been described above (page 399).

The integument covering the dorsum and sides of the nose is thin, and loosely connected with the subjacent parts, but where it forms the tip or lobe and the alae of the nose it is thicker and more firmly adherent. It is furnished with a large number of sebaceous follicles, the orifices of which are usually very distinct.

The mucous membrane lining the interior of the nose is continuous with the skin externally and with that which lines the nasal fossae within.

The arteries of the nose are the lateralis nasi from the facial, and the inferior artery of the septum from the superior coronary, which supply the alae and septum, the sides and dorsum being supplied from the nasal branch of the ophthalmic and the infra-orbital.

The veins of the nose terminate in the facial and ophthalmic.

The nerves of the nose are branches from the facial, infra-orbital, and infra-trochlear, and a filament from the nasal branch of the ophthalmic.

Nasal Fossae.

The nasal fossae are two irregular cavities situated in the middle of the face and extending from before backward. They open in front by the two anterior nares, and terminate in the pharynx, behind, by the posterior nares. The anterior nares are somewhat pear-shaped apertures, each measuring about one inch vertically and half an inch transversely at their widest part. The posterior nares are two oval openings situated at the upper part of the anterior wall of the pharynx. They are smaller in the body than in the skeleton, because narrowed by the mucous membrane. Each opening measures an inch in the vertical and half an inch in the transverse direction in a well-developed adult skull.
The mucous membrane lining the nasal fossae is called the pituitary, from the nature of its secretion; or Schneiderian, from Schneider, the first anatomist who showed that the secretion proceeded from the mucous membrane, and not, as was formerly imagined, from the brain. It is intimately adherent to the peristium or perichondrium, over which it lies. It is continuous externally with the skin through the anterior nares, and with the mucous membrane of the pharynx through the posterior nares. From the nasal fossae its continuity may be traced with the conjunctiva through the nasal duct and lacrymal canals; with the lining membrane of the tympanum and mastoid cells through the Eustachian tube; and with the frontal, ethmoidal, and sphenoidal sinuses, and the antrum of Highmore through the several openings in the meatuses. The mucous membrane is thickest and most vascular over the turbinated bones. It is also thick over the septum, but in the intervals between the spongy bones and on the floor of the nasal fossae it is very thin. Where it lines the various sinuses and the antrum of Highmore it is thin and pale.

Owing to the great thickness of this membrane, the nasal fossae are much narrower, and the turbinated bones, especially the lower ones, appear larger and more prominent than in the skeleton. From the same circumstance also the various apertures communicating with the meatuses are either narrowed or completely closed.

In the superior meatus the aperture of communication with the posterior ethmoidal cells is considerably diminished in size, and the sphenopalatine foramen completely covered in.

In the middle meatus the opening of the infundibulum is partially hidden by
a projecting fold of mucous membrane, and the orifice of the antrum is contracted to a small circular aperture, much narrower than in the skeleton.

In the inferior meatus the orifice of the nasal duct is partially hidden by either a single or double valvular mucous fold, and the anterior palatine canal either completely closed in or a tubular cul-de-sac of mucous membrane is continued a short distance into it. This cul-de-sac is termed the organ of Jacobson, and is present in all mammals as well as man. In the former it consists of a bilateral tube, situated in the nasal septum and supported by hyaline cartilage, the cartilage of Jacobson.

In the roof the opening leading to the sphenoidal sinus is narrowed, and the apertures in the cribriform plate of the ethmoid completely closed in.

Structure of the Mucous Membrane.—The epithelium covering the mucous membrane differs in its character according to the functions of the part of the nose in which it is found. Near the orifice of the nostril, the vestibule, where common sensation is chiefly or alone required, the epithelium is of the ordinary pavement or scaly variety. In the rest of the cavity, below the distribution of the olfactory nerves—i.e. in the respiratory portion of the nasal cavity—the epithelium is columnar and ciliated. This is the case also in the meatuses of the nose. In this region, beneath the epithelium and its basement membrane, is a fibrous layer infiltrated with lymph-corpuscles, so as to form in many parts a diffuse adenoid tissue, and beneath this a nearly continuous layer of smaller and larger glands, some mucous and some serous, the ducts of which open upon the surface. In the olfactory region—i.e. the region in which the terminal filaments from the olfactory nerves are distributed (see page 889)—the epithelial cells are columnar and, for the most part, non-ciliated; their free surface presents a sharp outline, and their deep extremity is prolonged into a process which runs inward, branching to communicate with similar processes from neighboring cells, so as to form a network in the deep part of the mucous membrane. Lying between them are cells (termed by Max Schultze, olfactory cells), which consist of a nucleated body and two processes, of which one runs outward between the columnar epithelial cells and projects on the surface of the mucous membrane; the other (the deep) process runs inward, is frequently beaded like a nerve-fibre, and is believed by most observers to be in connection with one of the terminal filaments of the olfactory nerve. Amongst

Fig. 525.—Horizontal section, high up, of the nasal fossa, viewed from above. (Cryer.)
the branched ends of the columnar cells there is a deep layer of epithelial cells of a conical shape, their broad end resting on the basement membrane, and their tapering extremity projecting between the other cells. Beneath the epithelium, extending through the thickness of the mucous membrane, is a layer of glands, the glands of Bowman, identical in structure with serous glands.

The mucous membrane is pigmented in the olfactory, but not in the other regions, being of a light yellow color, at least in the white races.\(^1\)

The arteries of the nasal fossæ are the anterior and posterior ethmoidal, from the ophthalmic, which supply the ethmoidal cells, frontal sinuses, and roof of the nose; a minute twig from the small meningeal; the sphenopalatine, from the internal maxillary, which supplies the mucous membrane covering the spongy bones, the meatuses, and septum; the inferior artery of the septum from the superior coronary of the facial; and the alveolar branch of the internal maxillary, which supplies the lining membrane of the antrum. The ramifications of these vessels form a close, plexiform network beneath and in the substance of the mucous membrane.

The veins of the nasal fossæ form a close network beneath the mucous membrane. They pass, some with the veins accompanying the sphenopalatine artery, through the sphenopalatine foramen, and others through the alveolar branch, to join the facial vein; some accompany the ethmoidal arteries and terminate in the ophthalmic vein; and, lastly, a few communicate with the veins in the interior of the skull through the foramina in the cribiform plate of the ethmoid bone and the foramen cecum.

The nerves are—the olfactory, the nasal branch of the ophthalmic, filaments from the anterior dental branch of the superior maxillary, the Vidian, naso-palatine, descending anterior palatine, and nasal branches of Meckel's ganglion.

The olfactory, the special nerve of the sense of smell, is distributed over the upper third of the septum and over the surface of the superior and middle spongy bones.

The nasal branch of the ophthalmic distributes filaments to the fore part of the septum and outer wall of the nasal fossæ.

Filaments from the anterior dental branch of the superior maxillary supply the inferior meatus and inferior turbinate bone.

The Vidian nerve supplies the upper and back part of the septum and superior spongy bone, and the upper anterior nasal branches from the sphenopalatine ganglion have a similar distribution.

The naso-palatine nerve supplies the middle of the septum.

The larger or anterior palatine nerve supplies the middle and lower spongy bones.

**Surgical Anatomy.**—Instances of congenital deformity of the nose are occasionally met with, such as complete absence of the nose, an aperture only being present, or perfect development on one side, and suppression or malformation on the other; or there may be imperfect apposition of the nasal bones, so that the nose presents a median cleft or furrow. Deformities which have been acquired are much more common, such as flattening of the nose, the result of

---

1 An interesting speculation has been suggested by Dr. W. Ogle, (Med. Chir. Trans., vol. liii, p. 277) as to the possible connection between the presence and abundance of this pigment and the perfection of the sense of smell.
syphilitic necrosis, or imperfect development of the nasal bones in cases of congenital syphilis, or a lateral deviation of the nose may result from fracture.

The skin over the ala and tip of the nose is thick and closely adherent to subjacent parts. Inflammation of this part is therefore very painful, on account of the tension. It is largely supplied with blood, and, the circulation here being terminal, vascular engorgement is liable to occur, especially in women at the menopause and in both sexes from disorders of digestion, exposure to cold, etc. The skin of the nose also contains a large number of sebaceous follicles, and these, as the result of intemperance, are apt to become affected and the nose reddened, congested, and irregularly swollen. To this the term "grog-blossom" is popularly applied. In some of these cases there is enormous hypertrophy of the skin and subcutaneous tissues, producing pendulous masses, termed lipomata nas. Epithelioma and rodent ulcer may attack the nose, the latter being the more common of the two. Lupus and syphilitic ulceration frequently attack the nose, and may destroy the whole of the cartilaginous portion. In fact, lupus vulgaris begins more frequently on the ala of the nose than in any other situation.

Cases of congenital occlusion of one or both nostrils, or adhesion between the ala and septum may occur, and may require immediate operation, since the obstruction much interferes with sucking. Bony closure of the posterior nares may also occur.

To examine the nasal cavities, the head should be thrown back and the nose drawn upward, the parts being dilated by some form of speculum. It can also be examined with the little finger or a probe, and in this way foreign bodies detected. A still more extensive examination can be made by Rouge's operation, which was introduced for the cure of ozena by the removal of any dead bone which may be present in this disease. The whole framework of the nose is lifted up by an incision made inside the mouth, through the junction of the upper lip with the bone; the septum nasi and the lateral cartilages are divided with strong scissors till the anterior nares are completely exposed. The posterior nares can be explored by reflected light from the mouth, by which the posterior nares can be illuminated. The examination is very difficult to carry out, and, as a rule, sufficient information regarding the presence of foreign bodies or tumors in the naso-pharynx can be obtained by the introduction of the finger behind the soft palate through the mouth. The septum of the nose may be displaced or deviate from the middle line: this may be the result of an injury or from some congenital defect in its development. Sometimes the deviation may be so great that the septum may come in contact with the outer wall of the nasal fossae, and may even become adherent to it, thus producing complete obstruction. Perforation of the septum is not an uncommon affection, and may arise from several causes: syphilitic or tubercular ulceration, blood-tumor or abscess of the septum, and especially in workmen exposed to the vapor of bichromate of potash, from the irritating and corrosive action of the fumes. When small, the perforation may cause a peculiar whistling sound during respiration. When large, it may lead to the falling in of the bridge of the nose.

Epistaxis is a very common affection in children. It is rarely of much consequence, and will almost always subside, but in the more violent hemorrhages of later life it may be necessary to plug the posterior nares. In performing this operation it is desirable to remember the size of the posterior nares. A ready method of regulating the size of the plug to fit the opening is to make it of the same size as the terminal phalanx of the thumb of the patient to be operated on.

Nasal polypi is a very common disease, and presents itself in three forms: the gelatinous, the fibrous, and the malignant. The first is by far the most common. It grows from the mucous membrane of the outer wall of the nasal fossa, where there is an abundant layer of highly vascular submucous tissue; rarely from the septum, where the mucous membrane is closely adherent to the cartilage and bone, without the intervention of much, if any, submucous tissue. Their most common seat is probably the middle turbinate bone. The fibrous polypus generally grows from the base of the skull behind the posterior nares or from the roof of the nasal fossae. The malignant polypi, both sarcomatous or carcinomatous, may arise in the nasal cavities and the naso-pharynx; or they may originate in the antrum, and protrude through its inner wall into the nasal fossa.

Rhinoliths, or nose-stones, may sometimes be found in the nasal cavities, from the formation of phosphate of lime upon either a foreign body or a piece of inspissated secretion.

THE EYE.

The eyeball is contained in the cavity of the orbit. In this situation it is securely protected from injury, whilst its position is such as to ensure the most extensive range of sight. It is acted upon by numerous muscles, by which it is capable of being directed to any part; it is supplied by vessels and nerves, and is additionally protected in front by several appendages, such as the eyebrow, eyelids, etc.

The eyeball is imbedded in the fat of the orbit, but is surrounded by a thin membranous sac, the capsule of Tenon, which isolates it, so as to allow of free movement.

The capsule of Tenon (tunica vaginalis oculi) may be regarded as a distinct
serous membrane, consisting of a parietal and visceral layer. The latter invests
the posterior part of the globe from the ciliary margin of the cornea backward to
the entrance of the optic nerve, and is connected to it by very delicate connective
tissue; the former (parietal) lines the hollow in the fat in which the eyeball is
imbedded. Both layers are lined on their free surfaces by endothelial cells. The
cavity between them is continuous with the spaces between the different layers
of the sheath of the optic nerve—that is to say, with the subarachnoidean between the
pia-matral and the arachnoidal sheath, and the subdural between the arachnoid and
dural sheath—and into it empty the lymphatic vessels of the sclerotic. The capsule
is pierced by the muscles of the eyeball near their insertion, and sends tubular
prolongations on them, which become continuous with the sheath of the muscles.
From the outer surface of these sheaths expansions, consisting of elastic fibres and
muscle-cells, are given off to the margin of the orbit, which serve to limit the
degree of contraction of the muscles.1

The eyeball is composed of segments of two spheres of different sizes. The
anterior segment is one of a small sphere, and forms about one-sixth of the eyeball.
It is more prominent than the posterior segment, which is one of a much larger
sphere, and forms about five-sixths of the globe. The segment of the larger sphere
is opaque, and formed by the sclerotic, the tunic of protection to the eyeball; the
smaller sphere is transparent, and formed by the cornea. The axes of the eyeballs
are nearly parallel, and do not correspond to the axes of the orbits, which are
directed outward. The optic nerves follow the direction of the axes of the orbits,
and are therefore not parallel; they enter the eyeball a little to their inner or nasal
side. The eyeball measures rather more in its transverse than in its antero-
posterior and vertical diameters, the former amounting to about an inch, the latter
to about nine-tenths of an inch.

The eyeball is composed of several investing tunics, and of fluid and solid
refracting media, called humors.

The tunics are three in number:

1. Sclerotic and Cornea.
2. Choroid, Iris, and Ciliary Processes.
3. Retina.

The refracting media, or humors, are also three:

Aqueous. Crystalline(lens) and Capsule. Vitreous.

The sclerotic and cornea form the external tunic of the eyeball; they are
essentially fibrous in structure, the sclerotic being opaque, and forming the
posterior five-sixths of the globe; the cornea, which forms the remaining sixth,
being transparent.

The Sclerotic (αξιορός, hard) (Fig. 527) has received its name from its extreme
density and hardness; it is a firm, unyielding, fibrous membrane, serving to main-
tain the form of the globe. It is much thicker behind than in front. Its external
surface is of a white color, quite smooth, except at the points where the Recti and
Obliqui muscles are inserted into it, and covered, for part of its extent, by the
conjunctival membrane; hence the whiteness and brilliancy of the front of the
eyeball. Its inner surface is stained of a brown color, marked by grooves, in
which are lodged the ciliary nerves, and connected by an exceedingly fine cellular
tissue (lamina fusca) with the outer surface of the choroid. Behind, it is pierced
by the optic nerve a little to its inner or nasal side, and is continuous with the
fibrous sheath of the nerve, which is derived from the dura mater. At the point
where the optic nerve passes through the sclerotic this membrane forms a thin
cribriform lamina (the lamina cribrosa); the minute orifices in this layer serve
for the transmission of the nervous filaments, and the fibrous septa dividing them
from one another are continuous with the membranous processes which separate
the bundles of nerve-fibres. One of these openings, larger than the rest, occupies

1 See a paper by Mr. C. B. Lockwood (Journal of Anatomy and Physiology, vol. xx., part i. p. 1).
the centre of the lamella; it is called the *porus opticus*, and transmits the *arteria centralis retinae* to the interior of the eyeball. Around the cribiform lamella are numerous small apertures for the transmission of the ciliary vessels and nerves. In front the sclerotic is continuous with the cornea by direct continuity of tissue, but the opaque sclerotic overlaps the cornea rather more on its outer than on its inner surface.

*Structure.*—The sclerotic is formed of white fibrous tissue intermixed with fine elastic fibres, and of flattened connective-tissue corpuscles, some of which are pigmented, contained in cell-spaces between the fibres. These fibres are aggregated into bundles which are arranged chiefly in a longitudinal direction. It yields gelatin on boiling. Its vessels are not numerous, the capillaries being of small size, uniting at long and wide intervals. The existence of nerves in it is doubtful.

![Diagram of the eye](image)

**FIG. 327.—A horizontal section of the eyeball.** (Allen.)

The **cornea** is the projecting transparent part of the external tunic of the eyeball, and forms the anterior sixth of the globe. It is almost circular in shape, occasionally a little broader in the transverse than in the vertical direction. It is convex anteriorly, and projects forward from the sclerotic in the same manner that a watch-glass does from its case. Its degree of curvature varies in different individuals, and in the same individual at different periods of life, it being more prominent in youth than in advanced life, when it becomes flattened. The cornea is dense and of uniform thickness throughout; its posterior surface is perfectly circular in outline, and exceeds the anterior surface slightly in extent, from the latter being overlapped by the sclerotic.

**Structure.**—The cornea consists of four layers—namely, (1) several strata of epithelial cells, continuous with those of the conjunctiva; (2) a thick central fibrous structure, the *cornea proper*; (3) a homogeneous elastic lamina; and (4) a single layer of epithelial cells, forming part of the lining membrane of the anterior chamber of the eyeball. The name of *membrane of Descemet* or *Demours* is given to this posterior elastic lamina and its endothelial coating.
The conjunctival epithelium, which covers the front of the cornea proper, consists of several strata of epithelial cells. The lowermost cells are columnar; then follow two or three layers of polyhedral cells, some of which present ridges and furrows similar to those found in the cuticle. Lastly, there are three or four layers of scaly epithelium with flattened nuclei.

The proper substance of the cornea is fibrous, tough, unyielding, perfectly transparent, and continuous with the sclerotic, with which it is identical in structure. It is composed of about sixty flattened lamellae, superimposed one on another. These lamellae are made up of bundles of fibrous connective tissue, the fibres of which are directly continuous with the fibres of the sclerotic. The fibres of each lamella are for the most part parallel with each other; those of alternating lamellae at right angles to each other. Fibres, however, frequently pass from one lamella to the next.

The lamellae are connected with each other by an interstitial cement-substance, in which are spaces, the corneal spaces. The spaces are stellate in shape, and have numerous offsets by which they communicate with other spaces. Each space contains a cell, the corneal corpuscle, which resembles in form the space in which it is contained, but does not entirely fill it.

Immediately beneath the conjunctival epithelium the cornea proper presents certain characteristic differences, which have led some anatomists to regard it as a distinct membrane, and it has been named by Bowman the anterior elastic lamina. It differs, however, from the true elastic lamina or membrane of Descemet in many essential particulars, presenting evidence of fibrillar structure, and not having the same tendency to curl inward or to undergo fracture when detached from the other layers of the cornea. It consists of extremely closely interwoven fibrils, similar to those found in the rest of the cornea proper, but contains no corneal corpuscles. It seems, therefore, more proper to regard it as a part of the proper tissue of the cornea.

The posterior elastic lamina, which covers the proper structure of the cornea behind, presents no structure recognizable under the microscope. It consists of a hard, elastic, and perfectly transparent homogeneous membrane, of extreme thinness, which is not rendered opaque by either water, alcohol, or acids. It is very brittle, but its most remarkable property is its extreme elasticity, and the tendency which it presents to curl up or roll upon itself, with the attached surface innermost, when separate from the proper substance of the cornea. Its use appears to be (as suggested by Dr. Jacob) "to preserve the requisite permanent curve of the flaccid cornea proper."

At the margin of the cornea this posterior elastic membrane breaks up into fibres to form a reticular structure at the outer angle of the anterior chamber, the intervals between the fibres forming small cavernous spaces, the spaces of Fontana. These little recesses communicate with a somewhat larger space in the substance of the sclerotic close to its junction with the cornea. This is the canal of Schlemm, or sinus circularis iridis, and, according to some authors, is a lymph-canal, but according to others is a venous sinus. Some of the fibres of this reticulated structure are continued into the front of the iris, forming the ligamentum pectinatum iridis, while others are connected with the fore part of the sclerotic and choroid.

The endothelial lining of the aqueous chamber covers the posterior surface of the posterior elastic lamina. It consists of a single layer of polygonal flattened transparent nucleated cells, similar to those found lining other serous cavities.

Arteries and Nerves.—The cornea is a non-vascular structure, the capillary vessels terminating in loops at its circumference. Lymphatic vessels have not as yet been demonstrated in it, but are represented by the channels in which the bundles of nerves run; these are lined by an endothelium and are continuous with the cell-spaces. The nerves are numerous, twenty-four to thirty-six in

1This layer has been called by Reichert the "anterior limiting layer"—a name which appears more applicable to it than that of "anterior elastic lamina."
number (Kölliker), forty to forty-five (Waldeyer and Sümisch); they are derived from the ciliary nerves and enter the laminated tissue of the cornea. They ramify throughout its substance in a delicate network, and their terminal filaments form a firm and closer plexus on the surface of the cornea proper beneath the epithelium. This is termed the subepithelial plexus, and from it fibrils are given off which ramify between the epithelial cells, forming a network which is termed the intra-epithelial plexus.

**Dissection.**—In order to separate the sclerotic and cornea, so as to expose the second tunic, the eyeball should be immersed in a small vessel of water and held between the finger and thumb. The sclerotic is then carefully incised, in the equator of the globe, till the choroid is exposed. One blade of a pair of probe-pointed scissors is now introduced through the opening thus made, and the sclerotic divided around its entire circumference, and removed in separate portions. The front segment being then drawn forward, the handle of the scalpel should be pressed gently against it at its connection with the iris, and, these being separated, a quantity of perfectly transparent fluid will escape; this is the aqueous humor. In the course of the dissection the ciliary nerves may be seen lying in the loose cellular tissue between the choroid and sclerotic or contained in delicate grooves on the inner surface of the latter membrane.

**Second Tunic.**—This is formed by the choroid behind, the iris and ciliary processes in front, and by the Ciliary muscle, opposite the junction of the sclerotic and cornea.

![Fig. 528.—The choroid and iris. (Enlarged.)](image)

The choroid is the vascular and pigmentary tunic of the eyeball investing the posterior five-sixths of the globe, and extending as far forward as the cornea, the ciliary processes being appendages of the choroid developed from its inner surface in front. The iris is the circular muscular septum which hangs vertically behind the cornea, presenting in its centre a large circular aperture, the pupil. The Ciliary muscle forms the white ring observed at the point where the choroid and iris join with each other and with the sclerotic and cornea.

The **Choroid** is a thin, highly vascular membrane, of a dark brown or chocolate color, which invests the posterior five-sixths of the central part of the globe. It is pierced behind by the optic nerve, and extends in front as far forward as the ciliary ligament, where it is connected with the iris, and bends inward, forming on its inner surface a series of folds or plaitings, the ciliary processes. It is thicker
behind than in front. Externally it is connected by a fine cellular web (*membrana fusca*) with the inner surface of the sclerotic. Its inner surface is smooth and lies in contact with the retina.

**Structure.**—The choroid consists mainly of a dense capillary plexus and of small arteries and veins, carrying the blood to and returning it from this plexus. On its external surface—*i. e.* the surface next the sclerotic—is a thin membrane of fine elastic fibres arranged in lamelle, which are covered with endothelium and form spaces, which communicate by perforations in the sclerotic, through which the vessels and nerves enter, with the capsule of Tenon. This layer is named the *lamina suprachoroidea*, and is continuous with the lamina fusca of the sclerotic.

Internal to this is the **choroid proper**, and, in consequence of the small arteries and veins being arranged on the outer surface of the capillary network, it is customary to describe this as consisting of two layers, the outermost composed of small arteries and veins, with pigment-cells interspersed between them, and the inner consisting of a capillary plexus. The **external layer** consists, in part, of the larger branches of the short ciliary arteries, which run forward between the veins before they bend inward to terminate in the capillaries; but is formed principally of veins, which are named, from their arrangement, *venae vorticosae*. They converge to four or five equidistant trunks, which pierce the sclerotic midway between the margin of the cornea and the entrance of the optic nerve. Interspersed between the vessels are lodged dark star-shaped pigment-cells, the fibrous offsets from which, communicating with similar branchings from neighboring cells, form a delicate network or stroma, which toward the inner surface of the choroid loses its pigmentary character. The **internal layer** consists of an exceedingly fine capillary plexus, formed by the short ciliary vessels, and is known as the *tunica Raysehiana*. The network is close, and finer at the hinder part of the choroid than in front. About half an inch behind the cornea its meshes become larger, and are continuous with those of the ciliary processes. On the inner surface of this tunic is a very thin, structureless—or, according to Kölliker, faintly fibrous—membrane, called the *lamina vitrea*; it is closely connected with the stroma of the choroid, and separates it from the pigmentary layer of the retina.

The ciliary processes should now be examined. They may be exposed, either by detaching the iris from its connection with the Ciliary muscle, or by making a transverse section of the globe and examining them from behind.

The **ciliary processes** are formed by the plaiting and folding inward of the various layers of the choroid (*i. e.* the choroid proper and the lamina vitrea) at its anterior margin, and are received between corresponding foldings of the suspensory
ligament of the lens, thus establishing a connection between the choroid and inner tunic of the eye. They are arranged in a circle, and form a sort of plaited frill behind the iris round the margin of the lens. They vary between sixty and eighty in number, lie side by side, and may be divided into large and small; the latter, consisting of about one-third of the entire number, are situated in the spaces between the former, but without regular alternation. The larger processes are each about one-tenth of an inch in length, and are attached by their periphery to the Ciliary muscle, and are continuous with the layers of the choroid; the opposite margin is free, and rests upon the circumference of the lens. Their anterior surface is turned toward the back of the iris, with the circumference of which they are continuous. The posterior surface is closely connected with the suspensory ligament of the lens.

**Structure.**—The ciliary processes are similar in structure to the choroid, but the vessels are larger, and have chiefly a longitudinal direction. They are covered on their inner surface with a layer of black pigment-cells continuous with the cells of the pigmented layer of the retina, and in their stroma are also other, stellate, pigment-cells, which, however, are not so numerous as in the choroid itself, and toward the free extremities of the folds are devoid of pigment.

The **Iris** (iris, a rainbow) has received its name from its various colors in different individuals. It is a thin, circular-shaped, contractile curtain, suspended in the aqueous humor behind the cornea and in front of the lens, being perforated a little to the nasal side of its centre by a circular aperture, the **pupil**, for the transmission of light. By its circumference it is intimately connected with the choroid; externally to this is the Ciliary muscle, by which it is connected to the sclerotic and cornea; its inner edge forms the margin of the pupil; its surfaces are flattened, and look forward and backward, the anterior surface toward the cornea, the posterior toward the ciliary processes and lens. The circumference of the iris is connected to the cornea by a reticulated structure denominated the **ligamentum pectinatum iridis**. The anterior surface of the iris is variously colored in different individuals, and marked by lines which converge toward the pupil. The posterior surface is of a deep purple tint, from being covered by dark pigment; it is hence named **uvea**, from its resemblance in color to a ripe grape.

**Structure.**—The iris is composed of the following structures:

1. In front is a layer of polyhedral cells on a delicate hyaline basement membrane. This layer is continuous with the epithelial layer of the membrane of Descemet, and in men with dark-colored irides the cells contain pigment-granules.

2. **Stroma.**—The stroma consists of fibres and cells. The former are made up
of fine delicate bundles of fibrous tissue, of which some few fibres have a circular direction at the circumference of the iris, but the chief mass consists of fibres radiating toward the pupil. They form, by their interlacement, a delicate mesh, in which the vessels and nerves are contained. Interspersed between the bundles of connective tissue are numerous branched cells with fine processes. Many of them in dark eyes contain pigment-granules, but in blue eyes and the pink eyes of albinos they are unpigmented.

3. The muscular fibre is involuntary, and consists of circular and radiating fibres. The circular fibres (sphincter of the pupil) surround the margin of the pupil on the posterior surface of the iris, like a sphincter, forming a narrow band about one-thirtieth of an inch in width, those near the free margin being closely aggregated; those more external somewhat separated, and forming less complete circles. The radiating fibres (dilator of the pupil) converge from the circumference toward the centre, and blend with the circular fibres near the margin of the pupil.

4. Pigment.—The situation of the pigment-cells differs in different irides. In the various shades of blue eyes the only pigment-cells are several layers of small round or polyhedral cells filled with dark pigment, situated on the posterior surface of the iris and continuous with the pigmentary lining of the ciliary processes. The color of the eye in these individuals is due to this coloring matter showing more or less through the texture of the iris. In the albinos even this pigment is absent. In the gray, brown, and black eye there are, as mentioned above, pigment-granules to be found in the cells of the stroma and in the epithelial layer on the front of the iris, to which the color of the eye is due.

The arteries of the iris are derived from the long and anterior ciliary and from the vessels of the ciliary processes (see page 570).

The nerves of the iris are derived from the ciliary branches of the lenticular ganglion and the long ciliary from the nasal branch of the ophthalmic division of the fifth. After reaching the iris in the manner described above (page 797) they form a plexus around the attached margin of the iris; from this are derived non-
medullated fibres which terminate in the circular and radiating muscular fibres. Their exact mode of termination has not been ascertained. Other fibres from the plexus terminate in a network on the anterior surface of the iris. The fibres derived from the motor root of the lenticular ganglion (third nerve) supply the circular fibres, while those derived from the sympathetic supply the radiating fibres.

Membrana Pupillaris.—In the fovea the pupil is closed by a delicate transparent vascular membrane, the membrana pupillaris, which divides the space into which the iris is suspended into two distinct chambers. This membrane contains numerous minute vessels, continued from the margin of the iris to those on the front part of the capsule of the lens. These vessels have a looped arrangement, and converge toward each other without anastomosing. Between the seventh and eighth months the membrane begins to disappear, by its gradual absorption from the centre toward the circumference, and at birth only a few fragments remain. It is said sometimes to remain permanent and produce blindness.

The Ciliary muscle (Bowman) consists of unstriped fibres: it forms a grayish, semitransparent, circular band, about one-eighth of an inch broad, on the outer surface of the fore part of the choroid. It is thickest in front, and gradually becomes thinner behind. It consists of two sets of fibres, radiating and circular. The former, much the more numerous, arise at the point of junction of the corneal and sclerotic, and, passing backward, are attached to the choroid opposite to the ciliary processes. One bundle, according to Waldeyer, is continued backward to be inserted into the sclerotic. The circular fibres are internal to the radiating ones, and to some extent unconnected with them, and have a circular course around the attachment of the iris. They are sometimes called the “ring muscle” of Müller, and were formerly described as the ciliary ligament. The Ciliary muscle is admitted to be the chief agent in accommodation—i. e. in adjusting the eye to the vision of near objects. Mr. Bowman believed that this was effected by its compressing the vitreous body, and so causing the lens to advance; but the view which now prevails is that the contraction of the muscle, by drawing on the ciliary processes, relaxes the suspensory ligament of the lens, thus allowing the anterior surface of the lens to become more convex. The pupil is at the same time slightly contracted.¹

The Retina is a delicate nervous membrane upon the surface of which the images of external objects are received. Its outer surface is in contact with the choroid, the inner surface with the vitreous body. Behind it is continuous with the optic nerve; it gradually diminishes in thickness from behind forward, and in front extends nearly as far forward as the Ciliary muscle, where it terminates by a jagged margin, the ora serrata. It is soft, and semitransparent in the fresh state, but soon becomes clouded, opaque, and of a pinkish tint. Exactly in the centre of the posterior part of the retina, and at a point corresponding to the axis of the eye, in which the sense of vision is most perfect, is a round, elevated, yellowish spot, called, after its discoverer, the yellow spot or limbus luteus (macula lutea) of Sömmering, having a central depression at its summit, the fovea centralis. The retina in the situation of the fovea centralis is exceedingly thin; so much so that the dark color of the choroid is distinctly seen through it; so that it presents more the appearance of a foramen, and hence the name “foramen of Sömmering” at first given to it. It exists only in man, the quadruped, and some saurian reptiles. About one-tenth of an inch to the inner side of the yellow spot is the point of entrance of the optic nerve (porus opticus); here the nervous substance is slightly raised so as to form an eminence (colliculus nervi optici); the arteria centralis retinae pierces its centre. This is the only part of the surface of the retina from which the power of vision is absent.

Structure.—The retina is an exceedingly complex structure, and, when examined microscopically by means of sections made perpendicularly to its surface,

¹ See explanation and diagram in Power’s Illustrations of Some of the Principal Diseases of the Eye, p. 500.
is found to consist of ten layers, which are named from within outward as follows:

1. Membrana limitans interna.
2. Fibrous layer, consisting of nerve-fibres.
3. Vesicular layer, consisting of nerve-cells.
4. Inner molecular, or granular, layer.
5. Inner nuclear layer.
6. Outer molecular, or granular, layer.
7. Outer nuclear layer.
8. Membrana limitans externa.
9. Layer of rods and cones (Jacob’s membrane).
10. Pigmentary layer.

1. The membrana limitans interna is the most internal layer of the retina, and is in contact with the hyaloid membrane of the vitreous humor. It is derived from the supporting framework of the retina, with which tissue it will be described.

2. The fibrous layer is made up of nerve-fibres, the direct continuation of the fibres of the optic nerve. This nerve therefore passes through all the other layers of the retina, except the one previously mentioned, to reach its destination in the fibrous layer. As the nerve passes through the lamina cribrosa of the sclerotic coat the fibres of which it is composed lay aside their medullary sheaths and are continued onward, through the choroid and retina, as simple axis-cylinders. When these non-medullated fibres reach the internal surface of the retina, they radiate from their point of entrance over the surface of the retina, grouped in bundles, and in many places, according to Michel, arranged in plexuses. The layer is thickest at the optic nerve entrance, and gradually diminishes in thickness toward the ora serrata.

3. The vesicular layer consists of a single layer of large ganglion-cells, except in the macula lutea, where there are several layers. The cells are somewhat flask-shaped; their rounded internal margin resting on the preceding layer, and sending off a single process, which is prolonged into the fibrous layer, and is believed to be continuous with a nerve-fibre. From the opposite extremity of the cell one or more thicker processes extend into the inner molecular layer, where they divide dichotomously and become lost in its reticulum, or, according to some, pass through this layer to reach the inner nuclear layer.

4. The inner molecular layer consists of a stratum of granular-looking substance, from which circumstance it is sometimes called the “inner granular” layer.
It is made up of a dense reticulum of minute fibrils, intermingled with the fine processes of the ganglion-cells and also processes derived from certain cells contained in the next layer, immediately to be described. No direct connection between these sets of processes has yet been demonstrated, but it is considered probable that they do communicate, and that there is therefore a direct connection between the ganglion-cells of the vesicular layer and the nuclear cells of the inner nuclear layer. Within the reticulum formed by these fibrils minute clear granules, of unknown nature, are imbedded.

5. The inner nuclear layer is made up of nuclear bodies, of which there are three different kinds: (1) A large number of oval nuclei, which are commonly regarded as bipolar nerve-cells, and are much more numerous than either of the other kind. They consist of a large oval nuclear body placed vertically to the surface, containing a distinct nucleolus: they are surrounded by a small amount of protoplasm, which is prolonged into two processes: one of these passes inward into the inner molecular layer, is varicose in appearance, and, as stated above, is believed to be continuous with the processes of the ganglion-cells. The other process passes outward into the outer molecular layer, and there bifurcates. According to some observers, the divisions thus formed communicate with the rod-and cone-fibrils (Merkel). (2) At the innermost part of this inner nuclear layer is a stratum of cells which are not branched. (3) Some few cells are also found in this layer connected with the fibres of Müller, and will be described with those structures.

6. The outer molecular layer is much thinner than the inner molecular layer, but, like it, consists of a dense network of minute fibrils, and presents the same granular appearance. It differs, however, from the inner molecular layer in containing branched stellate cells, the processes of which are extremely fine and exhibit varicosities like nerve-fibrils. They are therefore considered by Schultze to be ganglion-cells.

7. The Outer Nuclear Layer.—Like the inner nuclear layer, this layer contains several strata of clear oval nuclear bodies; they are of two kinds, and, on account of their being respectively connected with the rods and cones of Jacob's membrane.
are named rod-granules and cone-granules. The rod-granules are much the more numerous, and are placed at different levels throughout the layer. They present a peculiar cross-striped appearance, and have prolonged from either extremity a fine process: the outermost is continuous with a single rod of Jacob's membrane; the innermost passes inward toward the outer molecular layer, and terminates in an enlarged extremity, from which are given off a number of minute fibrils, which enter the outer molecular layer. In its course it presents numerous varicosities.

The cone-granules, fewer in number than the rod-granules, are placed close to the membrana limitans externa, and are closely connected with the cones of Jacob's membrane. They do not present any cross-stripping, but contain a pyriform nucleus, which almost completely fills the cell. From their inner extremity a thick process passes inward to the outer molecular layer, where, like the processes of the rod-cells, it terminates in an enlargement, from which are given off numerous fine fibrils which enter the outer molecular layer.

8. The Membrana Limitans Externa.—This layer, like the membrana limitans interna, is derived from the fibres of Müller, with which structures it will be described.

9. Jacob's Membrane (bacillary layer).—The elements which compose this layer are of two kinds, rods and cones, the former being much more numerous than the latter. The rods are solid, of nearly uniform size, and arranged perpendicularly to the surface. Each rod consists of two portions, an outer and inner, which are joined together by a cement-substance and are of about equal length. They differ from each other as regards refraction and in their behavior with coloring reagents, the inner portion becoming stained by carmine, iodine, etc., the outer portion remaining unstained. The outer portion of each rod is marked by transverse strie, and is made up of a number of thin disks superimposed on one another. It also exhibits faint longitudinal markings. The inner portion of each rod at its inner extremity, where it is joined to the processes of the rod-granules, is indistinctly granular; at its outer extremity it presents a fine longitudinal striation, being composed of fine, bright, highly refracting fibrils.

The cones are conical or flask-shaped, their broad ends resting upon the membrana limitans externa, the narrow pointed extremity being turned to the choroid. Like the rods, they are made up of two portions, outer and inner; the outer portion being a short conical process, which, like the outer segment of the rods, presents transverse strie. The inner portion resembles the inner portion of the rods in structure, presenting an outer striated and an inner granular appearance, but differs from it in size, being bulged out laterally and presenting a flask shape.

10. The Pigmentary Layer, or Tapetum Nigrum.—The most external layer of the retina, formerly regarded as a part of the choroid, consists of a single layer of hexagonal epithelium cells loaded with pigment-granules (Fig. 21). In the eyes of albinos the cells of the pigmentary layer are present, but they contain no coloring matter. In many of the mammals also, as in the horse, and many of the carnivora, there is no pigment in the cells of this layer, and the choroid possesses a beautiful iridescent lustre, which is termed the tapetum lucidum.

Connective-tissue Framework of the Retina.—Almost all these layers of the retina are connected together by a sort of supporting connective tissue, which has been named the fibres of Müller, or radiating fibres, from which the membrana limitans interna et externa are derived. These fibres are found stretched between the two limiting layers, "as columns between a floor and a ceiling," and passing through all the nervous layers except Jacob's membrane. They commence on the inner surface of the retina by a conical base, the edges of the bases of adjoining fibres being united, and thus forming a boundary-line which is the membrana limitans interna. As they pass through the various layers they present a roughness on their surface, as if a number of membranous processes had been abruptly broken off. By these they are continuous with the reticulum of the inner and outer molecular layer and with a sponge-like stroma, in which the nuclei of the inner nuclear layers are imbedded. In the inner nuclear layer each fibre of Müller
THE ORGANS OF SENSE.

presents a clear oval nucleus, referred to above, which is sometimes situated at the side of, sometimes altogether within, the fibre. In the outer nuclear layer the fibre breaks up into fine lamellae, which form a fenestrated or sponge-like tissue, in which the rod-and cone-granules are enclosed, and at the outer border of this layer these lamellae unite along a definite line, forming the membrana limitans externa.

Macula Lutea and Fovea Centralis.—The structure of the retina at the yellow spot presents some modifications. In the macula lutea (1) the nerve-fibres are wanting as a continuous layer; (2) the vesicular layer consists of several strata of cells, instead of a single layer; (3) in Jacob's membrane there are no rods, but only cones, and these are longer and narrower than in other parts; and (4) in the outer nuclear layer there are only cone-fibres, which are very long and arranged in curved lines. At the fovea centralis the only parts which exist are the cones of Jacob's membrane, the outer nuclear layer, the cone-fibres of which are almost horizontal in direction, and an exceedingly thin inner granular layer. The color of the spot seems to imbue all the layers except Jacob's membrane; it is of a rich yellow, deepest toward the centre, and does not appear to consist of pigment-cells, but simply a staining of the constituent parts.

At the ora serrata the layers of the retina for the most part terminate abruptly, and the radiating fibres of Müller, covered by the pigmentary layer, can be traced forward, as the pars ciliaris, to the iris. The fibres of Müller here present the appearance of columnar epithelial cells arranged in a single stratum.

The arteria centralis retinae and its accompanying vein pierce the optic nerve, and enter the globe of the eye through the porus opticus. It immediately divides
into four or five branches, which at first run between the hyaloid membrane and the nervous layer, but they soon enter the latter membrane, and pass forward, dividing dichotomously. From these branches a minute capillary plexus is given off, which does not extend beyond the inner nuclear layer. In the foetus a small vessel passes forward, through the vitreous humor, to the posterior surface of the capsule of the lens.

Humors of the Eye.

The aqueous humor completely fills the anterior and posterior chambers of the eyeball. It is small in quantity (scarcely exceeding, according to Petit, four or five grains in weight), has an alkaline reaction, in composition is little more than water, less than one-fiftieth of its weight being solid matter, chiefly chloride of sodium.

The anterior chamber is a space bounded in front by the cornea, behind by the front of the iris. The posterior chamber was the name formerly given to a space which was believed to exist between the iris in front and the capsule of the lens, its suspensory ligament, and the ciliary processes behind. It is now known that the posterior surface of the iris is in immediate contact with the lens throughout the greater part of its extent. The only space which remains to represent the posterior chamber is a narrow chink between the peripheral part of the iris, the suspensory ligament, and the ciliary processes.

In the adult these two chambers communicate through the pupil; but in the foetus in the seventh month, when the pupil is closed by the membrana pupillaris, the two chambers are quite separate.

The Vitreous Body.

The vitreous body forms about four-fifths of the entire globe. It fills the concavity of the retina, and is hollowed in front for the reception of the lens and its capsule. It is perfectly transparent, of the consistence of thin jelly, and is composed of an albuminous fluid enclosed in a delicate transparent membrane, the hyaloid. This membrane invests the surface of the vitreous body; at the pars ciliaris retinae it splits into two layers, an anterior, the suspensory ligament of the lens, and a posterior, which passes over the front of the vitreous body. It has been supposed, by Hannover, that from its inner surface numerous thin lamellae are prolonged inward in a radiating manner, forming spaces in which the fluid is contained. In the adult these lamellae cannot be detected even after careful microscopic examination; but in the foetus a peculiar fibrous texture pervades the mass, the fibres joining at numerous points, and presenting minute nuclear granules at their point of junction. In the centre of the vitreous humor, running from the position of the entrance of the optic nerve on the retina to the posterior surface of the lens, is a canal filled with fluid and lined by a prolongation of the hyaloid membrane. This is the canal of Stilling, and is the canal which in the embryonic vitreous humor conveyed the minute artery from the central artery of the retina to the back of the lens. The fluid from the vitreous body resembles nearly pure water; it contains, however, some salts and a little albumen.

The hyaloid membrane encloses the whole of the vitreous humor, that portion on its anterior surface, which is hollowed out for the reception of the lens, being the posterior layer just mentioned; while the anterior layer is the suspensory ligament. It is a delicate structureless membrane, except where it forms the suspensory ligament, where it contains longitudinal elastic fibres. Immediately beneath the hyaloid membrane are found small, granular, nucleated cells which are said to be possessed of amœboid movements.

In the foetus the centre of the vitreous humor presents a tubular canal, through which a minute artery passes along the vitreous body to the capsule of the lens. In the adult no vessels penetrate its substance, so that its nutrition must be carried on by the vessels of the retina and ciliary processes situated upon its exterior.
The Crystalline Lens and its Capsule.

The crystalline lens, enclosed in its capsule, is situated immediately behind the pupil, in front of the vitreous body, and surrounded by the ciliary processes, which slightly overlap its margin.

The capsule of the lens is a transparent, highly elastic, and brittle membrane which closely surrounds the lens. It rests, behind, in a depression in the fore part of the vitreous body; in front it is in contact with the free border of the iris, this latter receding from it at the circumference, thus forming the posterior chamber of the eye; and it is retained in its position chiefly by the suspensory ligament of the lens. The capsule is much thicker in front than behind, structureless in texture, and when ruptured the edges roll up with the outer surface innermost, like the elastic lamina of the cornea. The anterior surface of the lens is connected to the inner surface of the capsule by a single layer of transparent, polygonal, nucleated cells. At the circumference of the lens these cells undergo a change in form: they become elongated, and Babucin states that he can trace the gradual transition of the cells into proper lens-fibres, with which they are directly continuous. There is no epithelium on the posterior surface.

In the foetus a small branch from the arteria centralis retinae runs forward, as already mentioned, through the vitreous humor to the posterior part of the capsule of the lens, where its branches radiate and form a plexiform network which covers its surface, and they are continuous round the margin of the capsule with the vessels of the pupillary membrane and with those of the iris. In the adult no vessels enter its substance.

The lens is a transparent, double-convex body, the convexity being greater on the posterior than on the anterior surface. It measures about a third of an inch in the transverse diameter, and about one-fourth in the antero-posterior. It consists of concentric layers, of which the external in the fresh state are soft and easily detached; those beneath are firmer, the central ones forming a hardened nucleus. These laminae are best demonstrated by boiling, or immersion in alcohol. The same reagents demonstrate that the lens consists of three triangular segments, the sharp edges of which are directed toward the centre, the bases toward the circumference. The laminae consist of minute parallel fibres which are hexagonal prisms, the edges being dentated, and the dentations fitting accurately into each other; their breadth is about \( \frac{1}{1000} \)th of an inch. They run from the sutures or lines of junction of the triangular segments on the one surface to the periphery of the lens, and, curving round its margin, they terminate at the line of junction of the segments on the other. No fibres pass from pole to pole, but they are arranged in such a way that fibres which commence near the pole on the one aspect of the lens—that is to say, near the apex of the triangular segment—terminate near the peripheral extremity of the plane on the other, or near the base of the triangular segment, and vice versa. The fibres of the outer layers of the lens each contain a nucleus, which together form a layer (nuclear layer) on the surface of the lens, most distinct toward its circumference. The meridians, or lines of junction of the three segments, are composed of an amorphous granular substance which sometimes becomes opaque, when the lines are seen forming a distinct star on the lens. The lines on one surface do not lie immediately opposite those on the other, but are intermediate.

The changes produced in the lens by age are the following:

In the foetus its form is nearly spherical, its color of a slightly reddish tint, it is not perfectly transparent, and is so soft as to break down readily on the slightest pressure.
In the adult the posterior surface is more convex than the anterior; it is colorless, transparent, and firm in texture.

In old age it becomes flattened on both surfaces, slightly opaque, of an amber tint, and increases in density.

The suspensory ligament of the lens is a thin, transparent, membranous structure placed at first between the vitreous body and the ciliary processes of the choroid, and then passing from these same processes to the anterior surface of the lens near its circumference. It assists in retaining the lens in its position. Its outer surface presents a number of folds or plaitings in which the corresponding folds of the ciliary processes are received. These plaitings are arranged round the lens in a radiating form, and are stained by the pigment of the ciliary processes. The suspensory ligament is that part of the hyaloid membrane, which, as described above, is continued forward to the anterior part of the margin of the lens. It is covered on its outer surface by the pars ciliaris, or connective-tissue framework of the retina, prolonged forward from the ora serrata. That portion of this membrane which intervenes between the ciliary processes and the capsule of the lens forms part of the boundary of the posterior chamber of the eye. The posterior surface of this layer is turned toward the vitreous humor, being separated from it at the circumference of the lens by a space called the canal of Petit.

The canal of Petit is about one-tenth of an inch wide. It is bounded in front by the suspensory ligament; behind by the “posterior layer” of the hyaloid membrane, its base being formed by the capsule of the lens. When inflated with air it is sacculated at intervals, owing to the foldings on its anterior surface.

The arteries of the globe of the eye are the short, long, and anterior ciliary arteries and the arteria centralis retinae. They have been already described (see page 570).

The ciliary veins are seen on the outer surface of the choroid, and are named, from their arrangement, the vena vorticosae. They converge to four or five equidistant trunks, which pierce the sclerotic midway between the margin of the cornea and the entrance of the optic nerve. Another set of veins accompany the anterior ciliary arteries and open into the ophthalmic vein.

The ciliary nerves are derived from the nasal branch of the ophthalmic and from the ciliary or ophthalmic ganglion.

Surgical Anatomy.—Foreign bodies frequently get into the conjunctival sac and cause great pain, especially if they come in contact with the corneal surface during the movements of the lid and the eye on each other. The conjunctiva is frequently involved in severe injuries of the eyeball, but is seldom ruptured alone; the most common form of injury to the conjunctiva alone is from a blow either from fire, strong acids, or lime. In these cases union is liable to take place between the eyelid and the eyeball. The conjunctiva is often the seat of inflammation arising from many different causes, and the arrangement of the conjunctival vessels should be remembered as affording a means of diagnosis between this condition and injection of the sclerotic, which is present in inflammations of the deeper structures of the globe. The inflamed conjunctiva is bright red; the vessels are large and tortuous, and greatest at the circumference, shading off toward the corneal margin; they anastomose freely and form a dense network, and they can be emptied or displaced by gentle pressure.

From a surgical point of view the cornea may be regarded as consisting of three layers: (1) of an external epithelial layer, developed from the epiblast, and continuous with the external epithelial covering of the rest of the body, and therefore in its lesions resembling those of the epidermis and superficial layers of the derma; (2) of the cornea proper, derived from the mesoblast, and associated in its diseases with the fibro-vascular structures of the body; and (3) the posterior elastic layer with its endothelium, also derived from the mesoblast and having the characters of a serous membrane, so that inflammation of it resembles inflammation of the other serous and synovial membranes of the body.

The cornea contains no blood-vessels, except at its periphery, where numerous delicate loops, derived from the anterior ciliary arteries, may be demonstrated on the anterior surface of the cornea. The rest of the cornea is nourished by lymph, which gains access to the proper substance of the cornea and the posterior layer through the spaces of Fontana. This lack of a direct blood-supply renders the cornea very apt to inflame in the cachectic and ill-nourished. In cases of granular lids there is a peculiar affection of the cornea, called panama, in which the anterior layers of the cornea become vascularized, and a rich network of blood-vessels may be seen on the cornea; and in interstitial keratitis new vessels extend into the cornea, giving it a pinkish hue, to which the term “salmon patch” is applied. The cornea is richly supplied with
nerves, derived from the ciliary, which enter the cornea through the fore part of the sclerotic and form plexuses in the stroma, terminating between the epithelial cells by fine ends or in corpuscles. In cases of glaucoma the ciliary nerves may be pressed upon as they course between the choroid and sclerotic, and the cornea becomes anaesthetic. The sclerotic has very few blood-vessels and nerves. The blood-vessels are derived from the anterior ciliary, and form an open plexus in its substance. As they approach the corneal margin this arrangement is peculiar. Some branches pass through the sclerotic to the ciliary body; others become superficial and lie in the episcleral tissue, and form arches, by anastomosing with each other, some little distance behind the corneal margin. From these arches numerous straight vessels are given off, which run forward to the cornea, forming its marginal plexus. In inflammation of the sclerotic and episcleral tissue these vessels become conspicuous, and form a pinkish zone of straight vessels radiating from the corneal margin, commonly known as the zone of ciliary injection. In inflammation of the iris and ciliary body this zone is present, since the sclerotic rapidly becomes involved when these structures are inflamed. But in inflammation of the cornea the sclerotic is seldom much affected, though the cornea and sclerotic are structurally continuous. This would appear to be due to the fact that the nutrition of the cornea is derived from a different source from that of the sclerotic. The sclerotic may be ruptured subcutaneously without any laceration of the conjunctiva, and the rupture usually occurs near the corneal margin, where the tunic is thinnest. It may be complicated with lesions of adjacent parts—laceration of the choroid, retina, iris, or suspensory ligament of the lens—and is then often attended with hemorrhage into the anterior chamber, which masks the nature of the injury. In some cases the lens has escaped through the rent in the sclerotic, and has been found under the conjunctiva. Wounds of the sclerotic are always dangerous, and are often followed by inflammation, suppuration, and by syphilitic or granulomatous ulcers.

The function of the choroid is to provide nutrition for the retina and to convey vessels and nerves to the ciliary body and iris. Inflammation of the choroid is therefore followed by grave disturbance in the nutrition of the retina, and is attended with early interference with vision. In its diseases it bears a considerable analogy to those which affect the skin, and, like it, is one of the places from which melanotic sarcomata may grow. These tumors contain a large amount of pigment in their cells, and grow only from those parts where pigment is naturally present. The choroid may be ruptured without injury to the other tunics, as well as participating in general injuries of the eyeball. In cases of uncomplicated rupture the injury is usually at its posterior part, and is the result of a blow on the front of the eye. It is attended by considerable hemorrhage, which for a time may obscure vision, but in most cases this is restored as soon as the blood is absorbed.

The iris is the seat of a malformation, termed coloboma, which consists in a deficiency or cleft, which in a great number of cases is clearly due to an arrest in development. In these cases it is found at the lower aspect, extending directly downward from the pupil, and the gap frequently extends through the choroid to the entrance of the optic nerve. In some rarer cases the gap is found in other parts of the iris, and is then not associated with any deficiency of the choroid. The iris is abundantly supplied with blood-vessels and nerves, and is therefore very prone to become inflamed. And when inflamed, in consequence of the intimate relationship which exists between the vessels of the iris and choroid this latter tunic is very apt to participate in the inflammation. And, in addition, inflammation of adjacent structures, the cornea and sclerotic, is apt to spread into the iris. The iris is covered with epithelium, and parts of the character of a serous membrane, and, like these structures, is liable to pour out a plastic exudation when inflamed, and contract adhesions, either to the cornea in front (synchiae anterior), or to the capsule of the lens behind (synchiae posterior). In iritis the lens may become involved, and the condition known as secondary cataract may be set up. Tumors occasionally commence in the iris; of these, cysts, which are usually congenital and sarcomatous tumors, are the most common and require removal. Gummata are not unfrequently found in this situation. In some forms of injury of the eyeball, as the impact of a spent shot, the rebound of a twig, or a blow with a whip, the iris may be detached from the Ciliary muscle, the amount of detachment varying from the slightest degree to the separation of the whole iris from its ciliary connection.

The retina, with the exception of its pigment-layer and its vessels, is perfectly transparent, so as to be invisible when examined by the ophthalmoscope, so that its diseased conditions are recognized by its loss of transparency. In retinitis, for instance, there is more or less dense and extensive opacity of its structure, and not unfrequently extravasations of blood into its substance. Hemorrhages may also take place into the retina from rupture of a blood-vessel without inflammation.

The retina may become displaced from effusion of serum between it and the choroid or by blows on the eyeball, or may occur without apparent cause in progressive myopia, and in this case the ophthalmoscope shows an opaque, tremulous cloud. Ghiona, a form of sarcoma, and essentially a disease of early life, is occasionally met with in connection with the retina.

The lens has no blood-vessels, nerves, or connective tissue in its structure, and therefore is not subject to those morbid changes to which tissues containing these structures are liable. It does, however, present certain morbid or abnormal conditions of various kinds. Thus, variations in shape, absence of the whole or a part of the lens, and displacements are amongst its congenital defects. Opacities may occur from injury, senile changes, malnutrition, or errors in growth or development. Senile changes may take place in the lens, impairing its elasticity and render-
ing it harder than in youth, so that its curvature can only be altered to a limited extent by the Ciliary muscle. And, finally, the lens may be dislocated or displaced by blows upon the eyeball, and its relations to surrounding structures altered by adhesions or the pressure of new growths.

There are two particular regions of the eye which require special notice: one of these is known as the "filtration area," and the other as the "dangerous area." The filtration area is the circumcorneal zone immediately in front of the iris. Here are situated the cavernous spaces of Fontana, which communicate with the canal of Schlemm, through which the chief transudation of fluid from the eye is now believed to take place. The dangerous area of the eye is the region in the neighborhood of the ciliary body, and wounds or injuries in this situation are peculiarly dangerous; for inflammation of the ciliary body is liable to spread to many of the other structures of the eye, especially to the iris and choroid, which are intimately connected by nervous and vascular supplies. Moreover, wounds which involve the ciliary region are especially liable to be followed by sympathetic ophthalmia, in which destructive inflammation of one eye is excited by some irritation in the other.

The Appendages of the Eye.

The appendages of the eye (tutamina oculi) include the eyebrows, the eyelids, the conjunctiva, and the lachrymal apparatus—viz. the lachrymal gland, the lachrymal sac, and the nasal duct.

The eyebrows (supercilia) are two arched eminences of integument which surmount the upper circumference of the orbit on each side, and support numerous short, thick hairs, directed obliquely on the surface. In structure the eyebrows consist of thickened integument, connected beneath with the Orbicularis palpebrarum, Corrugator supercili, and Occipito-frontalis muscles. These muscles serve, by their action on this part, to control to a certain extent the amount of light admitted into the eye.

The eyelids (palpebrae) are two thin, movable folds placed in front of the eye, protecting it from injury by their closure. The upper lid is the larger and the more movable of the two, and is furnished with a separate elevator muscle, the Levator palpebrae superioris. When the eyelids are opened an elliptical space (fissura palpebrarum) is left between their margins, the angles of which correspond to the junction of the upper and lower lids, and are called canthi.

The outer canthus is more acute than the inner, and the lids here lie in close contact with the globe; but the inner canthus is prolonged for a short distance inward toward the nose, and the two lids are separated by a triangular space, the lacus lachrymalis. At the commencement of the lacus lachrymalis, on the margin of each eyelid, is a small conical elevation, the lachrymal papilla, or tubercle, the apex of which is pierced by a small orifice, the punctum lachrymale, the commencement of the lachrymal canal.

The eyelashes (cilia) are attached to the free edges of the eyelids; they are short, thick, curved hairs, arranged in a double or triple row at the margin of the lids: those of the upper lid, more numerous and longer than the lower, curve upward; those of the lower lid curve downward, so that they do not interlace in closing the lids. Near the attachment of the eyelashes are the openings of a number of glands, glands of Mohl, arranged in several rows close to the free margin of the lid. They resemble in structure a portion of a sweat-gland, and are regarded as the modified sweat-glands of this region.

Structure of the Eyelids.—The eyelids are composed of the following structures, taken in their order from without inward:

Integument, areolar tissue, fibres of the Orbicularis muscle, tarsal plate (cartilage), and its ligament, Meibomian glands and conjunctiva. The upper lid has, in addition, the aponeurosis of the Levator palpebrae.

The integument is extremely thin, and continuous at the margin of the lids with the conjunctiva.

The subcutaneous areolar tissue is very lax and delicate, seldom contains any fat, and is extremely liable to serous infiltration.

The fibres of the Orbicularis muscle, where they cover the palpebrae, are thin, pale in color, and possess an involuntary action.
The tarsal plates (cartilages)\(^1\) are two thin elongated plates of dense connective tissue about an inch in length. They are placed one in each lid, contributing to their form and support.

The superior, the larger, is of a semilunar form, about one-third of an inch in breadth at the centre, and becoming gradually narrowed at each extremity. Into the anterior surface of this plate the aponeurosis of the Levator palpebrae is attached.

The inferior tarsal plate, the smaller, is thinner and of an elliptical form.

The free or ciliary margin of these plates is thick, and presents a perfectly straight edge. The attached or orbital margin is connected to the circumference of the orbit by the fibrous membrane of the lids with which it is continuous. The outer angle of each plate is attached to the malar bone by the external palpebral or tarsal ligament. The inner angles of the two plates terminate at the commencement of the lacus lachrymalis, being fixed to the margins of the orbit by the tendo oculi.

The tarsal ligament, or fibrous membrane of the lids, is a layer of fibrous membrane beneath the Orbicularis, attached marginally to the edge of the orbit, where it becomes continuous with the periosteum, and centrally to the tarsal plate, near its ciliary margin, with the tissue of which it is continuous. It is thickest and densest at the outer part of the orbit. Upon its under surface is a layer of unstriped muscle, which in the upper lid passes from the aponeurosis of the Levator palpebrae muscle to the tarsal plate. This ligament serves to support the eyelids, and retains the tarsal plates in their position.

The Meibomian glands (Fig. 537) are situated upon the inner surface of the eyelids between the tarsal plates and conjunctiva, and may be distinctly seen through the mucous membrane on evertting the eyelids, presenting the appearance of parallel strings of pearls. They are about thirty in number in the upper eyelid, and somewhat fewer in the lower. They are imbedded in grooves in the inner surface of the tarsal plates, and correspond in length with the breadth of each plate; they are, consequently, longer in the upper than in the lower eyelid. Their ducts open on the free margin of the lids by minute foramina, which correspond in number to the follicles. The peculiar parallel arrangement of these glands, side by side, forms a smooth layer adapted to the surface of the globe, over which they constantly glide. The use of their secretion is to prevent adhesions of the lids.

Structure of the Meibomian Glands.—These glands are a variety of the cutaneous sebaceous glands, each consisting of a single straight tube or follicle, having a caecal termination, and with numerous small secondary follicles opening into it. The tubes consist of basement membrane, covered by a layer of scaly epithelium; the secondary follicles are lined by a layer of polyhedral cells continuous with the cells of the tube. The remainder of the follicle is filled with large polygonal cells charged with fat. They are thus identical in structure with the sebaceous glands.

The conjunctiva is the mucous membrane of the eye. It lines the inner surface of the eyelids, and is reflected over the fore part of the sclerotic and cornea. In each of these situations its structure presents some peculiarities.

The palpebral portion of the conjunctiva is thick, opaque, highly vascular, and covered with numerous papille, its deeper parts presenting a considerable amount of lymphoid tissue. At the margin of the lids it becomes continuous with the lining membrane of the ducts of the Meibomian glands, and, through the lachrymal canals, with the lining membrane of the lachrymal sac and nasal duct. At the outer angle of the upper lid it may be traced along the lachrymal ducts into the lachrymal gland, and at the inner angle of the eye it forms a semilunar fold, the plica semilunaris. The folds formed by the reflection of the conjunctiva from the lids on to the eye are called the superior and inferior palpebral folds, the

---

\(^1\)Recent observations have proved that the so-called "tarsal cartilages" do not contain any cartilage-cells, and that the name is a misnomer.
former being the deeper of the two. Upon the sclerotic the conjunctiva is loosely connected to the globe; it becomes thinner, loses its papillary structure, is transparent, and only slightly vascular in health. Upon the cornea the conjunctiva consists only of epithelium, constituting the anterior layer of the cornea (conjunctival epithelium) already described (see page 893). Lymphatics arise in the conjunctiva in a delicate zone around the cornea, from which the vessels run to the ocular conjunctiva.

At the point of reflection of the conjunctiva from the lid on to the globe of the eye, termed the fornix conjunctive, are a number of mucous glands which are much convoluted. They are chiefly found in the upper lid. Other glands, analogous to lymphoid follicles, and called by Henle trachoma glands, are found in the conjunctiva, and, according to Strohmeyer, are chiefly situated near the inner canthus of the eye. They were first described by Brush, in his description of Peyer’s patches of the small intestines, as “identical structures existing in the under eyelid of the ox.”

The nerves in the conjunctiva are numerous and form rich plexuses. According to Krause, they terminate in a peculiar form of tactile corpuscle, which he terms the “terminal bulb.”

The caruncula lachrymalis is a small, reddish, conical-shaped body, situated at the inner canthus of the eye, and filling up the small triangular space in this situation, the locus lachrymalis. It consists of a cluster of follicles similar in structure to the Meibomian, covered with mucous membrane, and is the source of the whitish secretion which constantly collects at the inner angle of the eye. A few slender hairs are attached to its surface. On the outer side of the caruncula is a slight semilunar fold of mucous membrane, the concavity of which is directed toward the cornea; it is called the plica semilunaris. Müller found smooth muscular fibres in this fold, and in some of the domesticated animals a thin plate of cartilage has been discovered. This structure is considered to be the rudiment of the third eyelid in birds, the membrana nictitans.

The Lachrymal Apparatus (Fig. 538).

The lachrymal apparatus consists of the lachrymal gland, which secretes the tears, and its excretory ducts, which convey the fluid to the surface of the eye. This fluid is carried away by the lachrymal canals into the lachrymal sac, and along the nasal duct into the cavity of the nose.

The lachrymal gland is lodged in a depression at the outer angle of the orbit, on the inner side of the external angular process of the frontal bone. It is of an
of the conjunctiva near its reflection on to the globe. These orifices are arranged in a row, so as to disperse the secretion over the surface of the membrane.

Structure of the Lachrymal Gland.—In structure and general appearance the lachrymal resembles the serous salivary glands (page 946). In the recent state the cells are so crowded with granules that their limits can hardly be defined. They contain an oval nucleus, and the cell-protoplasm is finely fibrillated.

The lachrymal canals commence at the minute orifices, puncta lachrymalia, on the summit of a small conical elevation, the lachrymal papilla, seen on the margin of the lids at the outer extremity of the lacus lachrymalis. The superior canal, the smaller and shorter of the two, at first ascends, and then bends at an acute angle, and passes inward and downward to the lachrymal sac. The inferior canal at first descends, and then, abruptly changing its course, passes almost horizontally inward to the lachrymal sac. These canals are dense and elastic in structure and somewhat dilated at their angle. The mucous membrane is covered with scaly epithelium.

The lachrymal sac is the upper dilated extremity of the nasal duct, and is lodged in a deep groove formed by the lachrymal bone and nasal process of the superior maxillary. It is oval in form, its upper extremity being closed in and rounded, whilst below it is continued into the nasal duct. It is covered by a fibrous expansion derived from the tendo oculi, and on the inner side it is crossed by the Tensor tarsi muscle (Horner's muscle, page 395), which is attached to the ridge on the lachrymal bone.

Structure.—It consists of a fibrous elastic coat, lined internally by mucous membrane, the latter being continuous, through the lachrymal canals, with the mucous lining of the conjunctiva, and, through the nasal duct, with the pituitary membrane of the nose.
The nasal duct is a membranous canal, about three-quarters of an inch in length, which extends from the lower part of the lachrymal sac to the inferior meatus of the nose, where it terminates by a somewhat expanded orifice, provided with an imperfect valve, the *value of Hauner*, formed by the mucous membrane. It is contained in an osseous canal formed by the superior maxillary, the lachrymal, and the inferior turbinated bones, is narrower in the middle than at each extremity, and takes a direction downward, backward, and a little outward. It is lined by mucous membrane, which is continuous below with the pituitary lining of the nose. This membrane in the lachrymal sac and nasal duct is covered with ciliated epithelium as in the nose.

**Surface Form.**—The palpebral fissure, or opening between the eyelids, is elliptical in shape, and differs in size in different individuals and in different races of mankind. In the Mongolian races, for instance, the opening is very small, merely a narrow fissure, and this makes the eyeball appear small in these races, whereas the size of the eye is relatively very constant. The normal direction of the fissure is slightly oblique, in a direction upward and outward, so that the outer angle is on a slightly higher level than the inner. This is especially noticeable in the Mongolian races, in whom, owing to the upward projection of the malar bone and the shortness of the external angular process of the frontal bone, the tarsal plate of the upper lid is raised at its outer part and gives an oblique direction to the palpebral fissure.

When the eyes are directed forward, as in ordinary vision, the upper part of the cornea is covered by the upper lid, and the lower margin of the cornea corresponds to the level of the lower lid, so that about the lower three-fourths of the cornea is exposed under ordinary circumstances. On the margins of the lids, about a quarter of an inch from the inner canthus, are two small openings, the *puncta lachrymalia*, the commencement of the lachrymal canals. They are best seen by exerting the eyelids. In the natural condition they are in contact with the conjunctiva of the eyeball, and are maintained in this position by the Tensor tarsi muscle, so that the tears running over the surface of the globe easily find their way into the lachrymal canals. The position of the lachrymal sac into which the canals open is indicated by a little tubercle (page 224), which is plainly to be felt on the lower margin of the orbit. The lachrymal sac lies immediately above and to the inner side of this tubercle, and a knife passed through the skin in this situation would open the cavity. The position of the lachrymal sac may also be indicated by the tendo oculi or internal tarsal ligament. If both lids be drawn outward, so as to tense the skin at the inner angle, a prominent cord will be seen beneath the tightened skin. This is the *tendo oculi*, which lies immediately above over the lachrymal sac, bisecting it, and thus forming a useful guide to its situation. A knife entered immediately beneath the tense cord would open the lower part of the sac. A probe introduced through this opening can be readily passed downward into the duct into the inferior meatus of the nose. The direction of the duct is downward, outward, and backward, and this course should be borne in mind in passing the probe, otherwise the point may be driven through the thin bony walls of the canal. A convenient plan is to direct the probe in such a manner that if it were pushed onward it would strike the first molar tooth of the lower jaw on the same side of the body. In other words, the surgeon standing in front of his patient should carry in his mind the position of the first molar tooth, and should push his probe onward in such a way as if he desired to reach this structure.

Beneath the internal angular process of the frontal bone the pulley of the Superior oblique muscle of the eye can be plainly felt by pushing the finger backward between the upper and inner angle of the eye and the roof of the orbit; passing backward and outward from this pulley, the tendon can be felt for a short distance.

**Surgical Anatomy.**—The eyelids are composed of various tissues, and consequently are liable to a variety of diseases. The skin which covers them is exceedingly thin and delicate, and is supported on a quantity of loose and lax subcutaneous tissue which contains no fat. In consequence of this it is very freely movable, and is liable to be drawn down by the contraction of neighboring cicatrices, and thus produce an eversion of the lid known as *ectropion*. Inversion of the lids (*entropion*) from spasm of the Orbicularis palpebrarum or from chronic inflammation of the palpebral conjunctiva may also occur. The eyelids are richly supplied with blood, and are often the seat of vascular growths, such as nevi. Rodent ulcer also frequently commences in this situation. The loose cellular tissue beneath the skin is liable to become extensively infiltrated either with blood or inflammatory products, producing very great swelling. Even from very slight injuries to this tissue the extravasation of blood may be so great as to produce considerable swelling of the lids and complete closure of the eye, and the same is the case when inflammatory products are poured out. The follicles of the eyelashes or the sebaceous glands associated with these follicles may be the seat of inflammation, constituting the ordinary "stye." The Meibomian glands are affected in the so-called "tarsal tumor;" the tumor, according to some, being caused by the retained secretion of these glands; by others it is believed to be a neoplasm connected with the gland. The ciliary follicles are liable to become inflamed, constituting the disease known as *blepharitis citraria*, or "bear-eye." Irregular or disorderly growth of the eyelashes not unfrequently occurs, some of them being turned toward the eyeball and producing inflammation and ulceration of the cornea, and possibly eventually complete destruction of the eye. The Orbicularis palpebrarum may be the seat of spasm, either in the form of slight quiv-
ering of the lids or repeated twitchings, most commonly due to errors of refraction in children, or more continuous spasm, due to some irritation of the fifth or seventh cranial nerve. The Orbicularis may be paralyzed, generally associated with paralysis of the other facial muscles. Under these circumstances the patient is unable to close the lids, and, if he attempts to do so, rolls the eyeball upward under the upper lid. The tears overflow from displacement of the lower lid, and the conjunctiva and cornea, being constantly exposed and the patient being unable to wink, become irritated from dust and foreign bodies. In paralysis of the Levator palpebrae superioris there is drooping of the upper eyelid and other symptoms of implication of the third nerve. The eyelids may be the seat of bruises, wounds, or burns. In these latter injuries adhesions of the margins of the lids to each other or adhesion of the lids to the globe may take place. The eyelids are sometimes the seat of emphysema after fracture of some of the thin bones forming the inner wall of the orbit. If shortly after such an injury the patient blows his nose, air is forced from the nostril through the lacerated structures into the connective tissue of the eyelids, which suddenly swell up and present the peculiar cracking characteristic of this affection.

The lachrymal gland is occasionally, though rarely, the seat of inflammation, either acute or chronic; it is also sometimes the seat of tumors, benign or malignant, and for these may require removal. This may be done by an incision through the skin just below the eyebrow; and the gland, being invested with a special capsule of its own, may be isolated and removed without: opening the general cavity of the orbit. The canaliculi may be obstructed, either as a congenital defect or by some foreign body, as an eyelash or a dacroyolith, causing the tears to run over the cheek. The canaliculi may also become seceded as the result of burns or injury; overflow of the tears may in addition result from deviation of the puncta or from chronic inflammation of the lachrymal sac. This latter condition is set up by some obstruction to the nasal duct frequently occurring in tubercular subjects. In consequence of this the tears and mucus accumulate in the lachrymal sac, distending it. Suppuration in the lachrymal sac is sometimes met with: this may be the sequel of a chronic inflammation; or may occur after some of the eruptive fevers in cases where the lachrymal passages were previously quite healthy. It may lead to lachrymal fistula.

THE EAR.

The organ of hearing is divisible into three parts—the external ear, the middle ear or tympanum, and the internal ear or labyrinth.

The external ear consists of an expanded portion named pinna or auricle, and the auditory canal, or meatus. The former serves to collect the vibrations of the air by which sound is produced; the latter conducts those vibrations to the tympanum.

The pinna, or auricle (Fig. 539), is of an ovoid form, with its larger end directed upward. Its outer surface is irregularly concave, directed slightly forward, and presents numerous prominences and depressions which result from the foldings of its fibro-cartilaginous element. To each of these names have been assigned. Thus the external prominent rim of the auricle is called the helix. Another curved prominence, parallel with and in front of the helix, is called the antihelix; this bifurcates above, so as to enclose a triangular depression, the fossa of the antihelix. The narrow curved depression between the helix and antihelix is called the fossa of the helix (fossa innominata or scaphoidea); the antihelix describes a curve round a deep, capacious cavity, the concha, which is partially divided into two parts by the commencement of the helix. In front of the concha, and projecting backward over the meatus, is a small pointed eminence, the tragus, so called from its being generally covered on its under surface with a tuft of hair resembling a goat's beard. Opposite the tragus, and separated from it by a deep notch (inexisura intertragica) is a small tubercle, the antitragus. Below this is the lobule, composed of tough areolar and adipose tissue, wanting the firmness and elasticity of the rest of the pinna.

Structure of the Pinna.—The pinna is composed of a thin plate of yellow fibro-cartilage covered with integument, and connected to the surrounding parts by the extrinsic ligaments and muscles, and to the commencement of the external auditory canal.

The integument is thin, closely adherent to the cartilage, and furnished with sebaceous glands, which are most numerous in the concha and scaphoid fossa.

The cartilage of the pinna consists of one single piece: it gives form to this part of the ear, and upon its surface are found all the depressions and eminences above described. It does not enter into the construction of all parts of the auricle: thus it does not form a constituent part of the lobule; it is deficient
also between the tragus and beginning of the helix, the notch between them being filled up by dense fibrous tissue. At the front part of the pinna, where the helix bends upward, is a small projection of cartilage, called the process of the helix. The cartilage of the pinna presents several intervals or fissures in its substance which partially separate the different parts. The fissure of the helix is a short vertical slit situated at the fore part of the pinna, immediately behind a small conical projection of cartilage, opposite the first curve of the helix (process of the helix). Another fissure, the fissure of the tragus, is seen upon the anterior surface of the tragus. The antihelix is divided below, by a deep fissure, into two parts: one part terminates by a pointed, tail-like extremity (processus caudatus); the other is continuous with the antitragus. The cartilage of the pinna is very pliable, elastic, of a yellowish color, and belongs to that form of cartilage which is known under the name of yellow fibro-cartilage.

The ligaments of the pinna consist of two sets: 1. The extrinsic set, or those connecting it to the side of the head. 2. The intrinsic set, or those connecting the various parts of its cartilage together.

The extrinsic ligaments, the most important, are two in number, anterior and posterior. The anterior ligament extends from the process of the helix to the root of the zygoma. A few fibres connect the tragus to the root of the zygoma. The posterior ligament passes from the posterior surface of the concha to the outer surface of the mastoid process of the temporal bone.

The intrinsic ligaments are also two in number. Of these, one is a strong fibrous band stretching across from the tragus to the commencement of the helix, completing the meatus in front and partly encircling the boundary of the concha; the other extends between the concha and the processus caudatus.

The muscles of the pinna (Fig. 540) consist of two sets: 1. The extrinsic, which connect it with the side of the head, moving the pinna as a whole—viz. the Attollens, Attrahens, and Retrahens aurem (page 594); and 2. The intrinsic, which extend from one part of the auricle to another—viz.:

The *Musculus helicis major* is a narrow vertical band of muscular fibres, situated upon the anterior margin of the helix. It arises below from the process of the helix, and is inserted into the anterior border of the helix, just where it is about to curve backward. It is pretty constant in its existence.

The *Musculus helicis minor* is an oblique fasciculus, attached to that part of the helix which commences from the bottom of the concha.

The *Tragiicus* is a short, flattened band of muscular fibres situated upon the outer surface of the tragus, the direction of its fibres being vertical.

The *Antitragicus* arises from the outer part of the antitragus: its fibres are inserted into the processus caudatus of the helix. This muscle is usually very distinct.

The *Transversus auriculae* is placed on the cranial surface of the pinna. It consists of radiating fibres, partly tendinous and partly muscular, extending from the convexity of the concha to the prominence corresponding with the groove of the helix.

The *Obliquus auris* (Todd) consists of a few fibres extending from the upper and back part of the concha to the convexity immediately above it.

The *arteries of the pinna* are—the posterior auricular from the external carotid, the anterior auricular from the temporal, and an auricular branch from the occipital artery.

The *veins* accompany the corresponding arteries.

The *nerves* are—the auricularis magnus, from the cervical plexus; the posterior auricular, from the facial to the muscles of the pinna; the auricular branch of the pneumogastric; the auriculo-temporal branch of the inferior maxillary nerve; the occipitalis minor from the cervical plexus; and the occipitalis major or internal branch of the posterior division of the second cervical nerve.

The *Auditory Canal* (*meatus auditorius externus*) extends from the bottom of the concha to the *membrana tympani*. It is about an inch and a quarter in length; its direction is obliquely forward, inward, and downward. At first it slightly ascends, while in the middle portion it makes a sharp bend backward. It forms an oval cylindrical canal, the greatest diameter being in the vertical direction at the external orifice, but in the transverse direction at the tympanic end. The calibre of the canal is narrowest about the middle. The *membrana tympani*, which occupies the termination of the meatus, is obliquely directed, in consequence of which the floor of the canal is longer than the roof, and the anterior wall longer than the posterior. The auditory canal is formed partly by cartilage and membrane, and partly by bone, and is covered by skin.

The *cartilaginous portion* is about half an inch in length, being rather less than half the canal; it is formed by the cartilage of the concha and tragus, prolonged inward, and firmly attached to the circumference of the auditory process of the temporal bone. The cartilage is deficient at its upper and back part, its place being supplied by fibrous membrane. This part of the canal is rendered extremely movable by two or three deep fissures (inseisur Santorini), which extend through the cartilage in a vertical direction.

The *osseous portion* is about three-quarters of an inch in length, and narrower than the cartilaginous portion. Its *inner end* is marked, except at its upper part, by a narrow groove (*sulcus tympanicus*) for the insertion of the *membrana tympani*. The bony ridge, external to the sulcus, is the remnant of the foetal tympanic ring. It also is deficient above, and this deficiency is known as the *notch of Rivinus*. The ends of the incomplete ring bound the notch, and are known as the *anterior* and *posterior tympanic spines*. Its *outer end* is dilated, and rough, in the greater part of its circumference, for the attachment of the cartilage of the pinna. Its vertical transverse section is oval, the greatest diameter being from above downward. The front and lower parts of this canal are formed by a curved plate (tympanic plate) of bone, which, in the fœtus, exists as a separate ring (tympanic ring) incomplete at its upper part.

The *skin* lining the meatus is very thin, adheres closely to the cartilaginous
and osseous portion of the tube, and covers the surface of the membrana tympani, forming its outer layer. After maceration the thin pouch of epidermis, when withdrawn, preserves the form of the meatus. In the thick subcutaneous tissue of the cartilaginous part of the meatus are numerous ceruminous glands, which secrete the ear-wax. They resemble in structure sweat-glands, and their ducts open on the surface of the skin.

The arteries supplying the meatus are branches from the posterior auricular, internal maxillary, and temporal.

The nerves are chiefly derived from the auriculo-temporal branch of the inferior maxillary nerve.

**Surface Form.**—At the point of junction of the osseous and cartilaginous portions the tube forms an obtuse angle, which projects into the tube at its antero-inferior wall. This produces a sort of constriction in this situation, and renders it the narrowest portion of the canal—an important point to be borne in mind in connection with the presence of foreign bodies in the ears. The cartilaginous is connected to the bony part by fibrous tissue, which renders the outer part of the tube very movable, and therefore by drawing the pinna upward and backward the canal is rendered almost straight. At the external orifice are a few short, crisp hairs which serve to prevent the entrance of small particles of dust, or flies or other insects. In the external auditory meatus the secretion of the ceruminous glands serves to catch any small particles which may find their way into the canal, and prevent their reaching the membrana tympani, where their presence might excite irritation. In young children the meatus is very short, the osseous part being very deficient, and consisting merely of a bony ring (the tympanic plate), which supports the membrana tympani. In the fetus the osseous part is entirely absent. The shortness of the canal in children should be borne in mind in introducing the aural speculum, so that it be not pushed in too far, at the risk of injuring the membrana tympani; indeed, even in the adult the speculum should never be introduced beyond the constriction which marks the junction of the osseous and cartilaginous portions. In using this instrument it is advisable that the pinna should be drawn upward, backward, and a little outward, so as to render the canal as straight as possible, and thus assist the operator in obtaining, by the aid of reflected light, a good view of the membrana tympani. Just in front of the membrane is a well-marked depression, situated on the floor of the canal and bounded by a somewhat prominent ridge; in this foreign bodies may become lodged. By aid of the speculum combined with traction of the auricle upward and backward, the whole of the membrana tympani is rendered visible. It is a pearly-gray membrane, slightly glistening in the adult, placed obliquely, so as to form with the floor of the meatus a very acute angle, while with the roof it forms an obtuse angle. At birth it is more horizontal, situated in almost the same plane as the base of the skull. About midway between the anterior and posterior margins of the membrane, and extending from the centre obliquely upward, is a reddish-yellow streak; this is the handle of the malleus, which is inserted into the membrane. At the upper part of this streak, close to the roof of the meatus, a little white rounded prominence is plainly to be seen: this is the processus brevis of the malleus, projecting against the membrane. The membrana tympani does not present a plane surface; on the contrary, its centre is drawn inward, on account of its connection with the handle of the malleus, and thus the external surface is rendered concave.
Middle Ear, or Tympanum.

The middle ear, or tympanum, is an irregular cavity, compressed from without inward, and situated within the petrous bone. It is placed above the jugular fossa; the carotid canal lying in front, the mastoid cells behind, the meatus auditorius externally, and the labyrinth internally. It is filled with air, and communicates with the pharynx by the Eustachian tube. The tympanum is traversed by a chain of movable bones, which connect the membrana tympani with the labyrinth, and serve to convey the vibrations communicated to the membrana tympani across the cavity of the tympanum to the internal ear.

The cavity of the tympanum measures about five lines from before backward, three lines in the vertical direction, and between two and three in the transverse, being a little broader behind and above than it is below and in front. It is bounded externally by the membrana tympani and meatus, internally, by the outer surface of the internal ear, and communicates, behind, with the mastoid cells, and in front with the Eustachian tube and canal for the Tensor tympani. Its roof and floor are formed by thin osseous laminae, the one forming the roof being a thin plate situated on the anterior surface of the petrous portion of the temporal bone, close to its angle of junction with the squamous portion of the same bone.

The roof is broad, flattened, and formed of a thin plate of bone which separates the cranial and tympanic cavities.

The floor is narrow, and corresponds to the jugular fossa, which lies beneath. It presents, near the inner wall, a small aperture for the passage of Jacobson's nerve.

The outer wall is formed mainly by the membrana tympani, partly by the ring of bone into which this membrane is inserted. Close to it are three small apertures—the iter chordae posterius, the Glaserian fissure, and the iter chordae anterius.

The aperture of the iter chordae posterius is in the angle of junction between the posterior and external walls of the tympanum, immediately behind the membrana tympani and on a level with its centre; it leads into a minute canal, which descends in front of the aqueductus Fallopii and terminates in that canal near the stylo-mastoid foramen. Through it the chorda tympani nerve enters the tympanum.

The Glaserian fissure opens just above and in front of the ring of bone into which the membrana tympani is inserted; in this situation it is a mere slit about a line in length. It lodges the long process of the malleus and gives passage to some tympanic vessels.

The aperture of the iter chordae anterius is seen just above the preceding fissure; it leads into a canal (canal of Hugnier), which runs parallel with the Glaserian fissure. Through it the chorda tympani nerve leaves the tympanum.

The internal wall of the tympanum (Fig. 542) is vertical in direction and looks directly outward. It presents for examination the following parts:

- Fenestra ovalis.
- Fenestra rotunda.
- Ridge of the aqueductus Fallopii.
- Promontory.

The fenestra ovalis is a reniform opening leading from the tympanum into the vestibule; its long diameter is directed horizontally, and its convex border is upward. The opening in the recent state is occupied by the base of the stapes, which is connected to the margin of the foramen by an annular ligament.

The fenestra rotunda is an aperture placed at the bottom of a funnel-shaped depression leading into the cochlea. It is situated below and rather behind the fenestra ovalis, from which it is separated by a rounded elevation, the promontory; it is closed in the recent state by a membrane (membrana tympani secundaria, Scarpa). This membrane is concave toward the tympanum, convex toward the cochlea. It consists of three layers: the external, or mucous, derived from the mucous lining of the tympanum; the internal, or serous, from the lining membrane of the cochlea; and an intermediate, or fibrous layer.

The promontory is a rounded hollow prominence, formed by the projection outward of the first turn of the cochlea; it is placed between the fenestrae, and
is furrowed on its surface by three small grooves which lodge branches of the tympanic plexus.

The rounded eminence of the aqueductus Fallopii, the prominence of the bony canal in which the portio dura is contained, traverses the inner wall of the tympanum above the fenestra ovalis, and behind that opening curves nearly vertically downward along the posterior wall.

The posterior wall of the tympanum is wider above than below, and presents for examination the Opening of the mastoid antrum.

Pyramid.

The mastoid antrum is an irregular cavity with several small apertures opening into it, situated above and behind the tympanum proper; the smaller openings lead into canals which communicate with large irregular cavities contained in the interior of the mastoid process. These cavities vary considerably in number, size, and form; they are lined by mucous membrane continuous with that lining the cavity of the tympanum. Just below the opening of the antrum is the pyramid. The antrum really opens into an upward and backward prolongation of the tympanum, known as the attic or epitympanic recess, in which are situated the head of the malleus and greater part of the incus (Fig. 543).

The pyramid is a conical eminence situated immediately behind the fenestra ovalis, and in front of the vertical portion of the Fallopian eminence above described; it is hollow in the interior, and contains the Stapedius muscle; its summit projects forward toward the fenestra ovalis, and presents a small aperture which transmits the tendon of the muscle. The cavity in the pyramid is prolonged into a minute canal, which communicates with the aqueductus Fallopii and transmits the nerve which supplies the Stapedius.

The anterior wall of the tympanum corresponds to the carotid canal, from which it is separated by a thin plate of bone. It presents the Canal for the Tensor tympani muscle. Orifice of the Eustachian tube.

The processus cochleariformis.

The orifices of the canal for the Tensor tympani muscle and of the Eustachian tube are separated from each other by a thin, delicate, horizontal plate of bone, the processus cochleariformis. These canals run from the tympanum, forward, inward, and a little downward, to the retiring angle between the squamous and petrous portions of the temporal bone.

The canal for the Tensor tympani muscle is the superior and the smaller of the two; it is rounded, and lies beneath the upper surface of the petrous bone, close to the hiatus Fallopii (Fig. 542).

The Eustachian tube is the channel through which the tympanum communicates with the pharynx. Its length is from an inch and a half to two inches, and its direction downward, forward, and inward. It is formed partly of bone, partly of cartilage and fibrous tissue.
The osseous portion is about half an inch in length. It commences in the lower part of the anterior wall of the tympanum, below the processus cochleariformis, and, gradually narrowing, terminates in an oval dilated opening at the angle of junction of the petrous and squamous portions, its extremity presenting a jagged margin which serves for the attachment of the cartilaginous portion.

The cartilaginous portion, about an inch in length, is formed of a triangular plate of elastic fibro-cartilage, curled upon itself, an interval being left below, between the margins of the cartilage, which is completed by fibrous and muscular tissue. Its canal is narrow behind, wide, expanded, and somewhat trumpet-shaped in front, terminating by an oval orifice at the upper part and side of the pharynx, behind the back part of the inferior meatus. Through this canal the mucous membrane of the pharynx is continuous with that which lines the tympanum. The mucous membrane is covered with ciliated epithelium (Fig. 544).

The membrana tympani separates the cavity of the tympanum from the bottom of the outer meatus. It is a thin, semi-transparent membrane, nearly oval in form, somewhat broader above than below, and directed very obliquely downward and inward. Its circumference is contained in a groove at the inner end of the meatus, which skirts the circumference of this part, excepting above. The portion filling in the notch of Rivinus (see above) is looser in texture than the remainder, and is known as the membrana flaccida. The handle of the malleus descends vertically between the inner and middle layers of this membrane as far down as its centre, where it is firmly attached, drawing the membrane inward, so that its outer surface is concave, its inner convex. The middle of the concavity is known as the umbo.

Structure.—This membrane is composed of three layers, an external (cuticular), a middle (fibrous), and an internal (mucous). The cuticular lining is derived from the integument lining the meatus. The fibrous layer consists of fibrous and elastic tissues; some of the fibres radiate from near the centre to the circumference; others are arranged, in the form of a dense circular ring, round the attached margin of the membrane. The mucous lining is derived from the mucous lining of the tympanum. The vessels pass to the membrana tympani along the handle of the malleus, and are distributed between its layers.

Ossicles of the Tympanum (Fig. 545).

The tympanum is traversed by a chain of movable bones three in number, the malleus, incus, and stapes. The former is attached to the membrana tympani, the latter to the fenestra ovalis, the incus being placed between the two, to both of which it is connected by delicate articulations.

The Malleus, so named from its fancied resemblance to a hammer, consists of a head, neck, and three processes—the handle or manubrium, the processus gracilis, and the processus brevis.

The head is the large upper extremity of the bone; it is oval in shape, and articulates posteriorly with the incus, being free in the rest of its extent.

The neck is the narrow contracted part just beneath the head, and below this is a prominence to which the various processes are attached.

The manubrium is a vertical process of bone which is connected by its outer margin with the membrana tympani. It decreases in size toward its extremity, where it is curved slightly forward, and flattened from within outward. On the
inner side. near its upper end, is a slight projection, into which the tendon of the Tensor tympani is inserted.

The processus gracilis is a long and very delicate process which passes from the eminence below the neck forward and outward to the Glaserian fissure, to which it is connected by bone and ligamentous fibres.

The processus brevis is a slight conical projection which springs from the root of the manubrium, and lies in contact with the membrana tympani.

The incus has received its name from its supposed resemblance to an anvil, but it is more like a bicuspid tooth, with two roots, which differ in length and are widely separated from each other. It consists of a body and two processes.

The body is somewhat quadrilateral, but compressed laterally. On the anterior surface of its summit is a deeply concavo-convex facet, which articulates with the malleus; in the fresh state it is covered with cartilage and lined with synovial membrane.

The two processes diverge from one another nearly at right angles.

The short process, somewhat conical in shape, projects nearly horizontally backward, and is attached to the margin of the opening leading into the mastoid cells by ligamentous fibres.

The long process, longer and more slender than the preceding, descends nearly vertically behind and parallel to the handle of the malleus, and, bending inward, terminates in a rounded globular projection, the os orbiculare, or lenticular process, which is tipped with cartilage and articulates with the head of the stapes. In the fetus the os orbiculare exists as a separate bone, but becomes united to the long process of the incus in the adult.

The Stapes, so called from its close resemblance to a stirrup, consists of a head, neck, two branches, and a base. The head presents a depression, tipped with cartilage, which articulates with the os orbiculare. The neck, the constricted part of the bone below the head, receives the insertion of the Stapedius muscle. The two branches (crura) diverge from the neck, and are connected at their extremities by a flattened, oval-shaped plate (the base), which forms the foot of the stirrup, and is fixed to the margin of the fenestra ovalis by ligamentous fibres.

Ligaments of the Ossicula.—These small bones are connected with each other and with the walls of the tympanum by ligaments, and moved by small muscles. The articular surfaces of the malleus and incus and the orbicular process of the incus and head of the stapes are covered with cartilage, connected together by delicate capsular ligaments and lined by synovial membrane. The ligaments connecting the ossicula with the walls of the tympanum are four in number—two for the malleus, one for the incus, and one for the stapes.

The anterior ligament of the malleus was formerly described by Sömmering as a muscle (Laxator tympani). It is now, however, believed by most observers to consist of ligamentous fibres only. It is attached by one extremity to the neck of the malleus, just above the processus gracilis, and by the other to the anterior wall of the tympanum, close to the Glaserian fissure, some of its fibres being prolonged through the fissure.

The suspensory ligament of the malleus is a delicate, round bundle of fibres which descends perpendicularly from the roof of the tympanum to the head of the malleus.

The posterior ligament of the incus is a short, thick, ligamentous band which connects the extremity of the short process of the incus to the posterior wall of the tympanum, near the margin of the opening of the mastoid cells.

The annular ligament of the stapes connects the circumference of the base of this bone to the margin of the fenestra ovalis.
A suspensory ligament of the incus has been described by Arnold, descending from the roof of the tympanum to the upper part of the incus, near its articulation with the malleus.

The muscles of the tympanum are two:

Tensor tympani.  

Stapedius.

The Tensor tympani, the larger, is contained in the bony canal above the osseous portion of the Eustachian tube, from which it is separated by the processus cochleariformis. It arises from the under surface of the petrous bone, from the cartilaginous portion of the Eustachian tube, and from the osseous canal in which it is contained. Passing backward through the canal, it terminates in a slender tendon which enters the tympanum and makes a sharp bend outward round the extremity of the processus cochleariformis, and is inserted into the handle of the malleus near its root. It is supplied by a branch from the otic ganglion.

The Stapedius arises from the side of a conical cavity hollowed out of the interior of the pyramid; its tendon emerges from the orifice at the apex of the pyramid, and, passing forward, is inserted into the neck of the stapes. Its surface is aponeurotic, its interior fleshy, and its tendon occasionally contains a slender bony spine, which is constant in some mammalia. It is supplied by the tympanic branch of the facial nerve.

Actions.—The Tensor tympani draws the membrana tympani inward and thus heightens its tension. The Stapedius draws the head of the stapes backward, and thus causes the base of the bone to rotate on a vertical axis drawn through its own centre; in doing this the back part of the base would be pressed inward toward the vestibule, while the fore part would be drawn from it. It probably compresses the contents of the vestibule.

The mucous membrane of the tympanum is thin, slightly vascular, and continuous with the mucous membrane of the pharynx through the Eustachian tube. It invests the ossicula and the muscles and nerves contained in the tympanic cavity, forms the internal layer of the membrana tympani, covers the foramen rotundum, and is reflected into the mastoid cells, which it lines throughout. In the tympanum and mastoid cells this membrane is pale, thin, slightly vascular, and covered with ciliated epithelium. In the osseous portion of the Eustachian tube the membrane is thin, but in the cartilaginous portion it is very thick, highly vascular, covered with laminar ciliated epithelium, and provided with numerous mucous glands.

The arteries supplying the tympanum are six in number. Three of them are larger than the rest—viz. the tympanic branch of the internal maxillary, which supplies the membrana tympani; the Vidian and the stylo-mastoid branch of the posterior auricular, which supplies the back part of the tympanum and mastoid cells. The smaller branches are—the petrosal branch of the middle meningeal, which enters through the hiatus Fallopii; a branch from the ascending pharyngeal, and another from the Vidian which pass up the Eustachian tube; and the tympanic branch from the internal carotid, given off in the carotid canal and perforating the thin anterior wall of the tympanum.

The veins of the tympanum terminate in the temporo-maxillary vein and in the superior petrosal sinus.

The nerves of the tympanum may be divided into—1, those supplying the muscles; 2, those distributed to the lining membrane; 3, branches communicating with other nerves.

Nerves to Muscles.—The Tensor tympani is supplied by a branch from the otic ganglion; the Stapedius, by the tympanic branch of the facial (Sömmerring).

The nerves distributed to the lining membrane are derived from the tympanic plexus.

The communications which take place in the tympanum are between the tympanic branch of the glosso-pharyngeal with the sympathetic and with filaments derived from the intumescentia ganglioformis of the facial.

The tympanic branch of the glosso-pharyngeal (Jacobson's nerve) enters the
tympanum by an aperture in its floor, close to the inner wall, and divides into branches which are contained in grooves upon the surface of the promontory forming the tympanic plexus.

Its branches of distribution are—one to the fenestra rotunda, one to the fenestra ovalis, and one to the lining membrane of the tympanum and Eustachian tube.

Its branches of communication are three, and occupy separate grooves on the surface of the promontory. One branch, the small deep petrosal, arches forward and downward to the carotid canal to join the carotid plexus. A second, the long petrosal nerve, runs forward through a canal close to or in the processus cochleariformis, and enters the foramen lacerum medium, where it joins the carotid plexus of the sympathetic, and generally the large superficial petrosal nerve. The third branch runs upward through the substance of the petrous portion of the temporal bone. In its course it passes by the gangliform enlargement of the facial nerve, and, receiving a connecting filament from it, becomes the small superficial petrosal nerve. It then enters the skull through a small aperture, situated external to the hiatus Fallopii on the anterior surface of the petrous bone, courses forward across the base of the skull, and emerges through a foramen in the middle fossa (sometimes through the foramen ovale) and joins the otic ganglion.

The chorda tympani leaves the facial about a quarter of an inch above the exit of the latter. It enters the tympanum through the iter chordæ posterius, and becomes invested with mucous membrane. It passes forward, between the handle of the malleus and vertical ramus of the incus, and leaves the tympanum through the iter chordæ anterius.

The Internal Ear, or Labyrinth (Fig. 546).

The internal ear has two main divisions, the osseous and membranous labyrinths. They are called labyrinths from the complexity of their shapes. The osseous labyrinth consists of three parts—the vestibule, semicircular canals, and cochlea. It is formed by a series of cavities channelled out of the substance of the petrous bone, communicating externally with the cavity of the tympanum through the fenestra ovalis and rotunda, and internally with the meatus auditorius internus, by means of minute bony canals which contain the auditory nerve-filaments. Within the osseous labyrinth is contained the membranous labyrinth, upon which the ramifications of the auditory nerve are distributed.

The Vestibule (Fig. 547) is the common central cavity of communication between the parts of the internal ear. It is situated on the inner side of the tympanum, behind the cochlea, and in front of the semicircular canals. It is somewhat ovoidal in shape from before backward, flattened from within outward, and measures about one-fifth of an inch from before backward, as well as from above downward, being narrower from without inward. On its outer or tympanic wall is the fenestra ovalis, closed, in the recent state, by the base of the stapes and its annular ligament. On its inner wall, at the fore part, is a small circular depression, fovea hemispherica, which is perforated, at its anterior and inferior part, by several minute holes (macula cribrosa) for the passage of the filaments of the auditory nerve; and behind this depression is a vertical ridge, the pyramidal eminence (crista vestibuli). At the hinder part of the inner wall is the orifice of the aque ductus vestibuli, which extends to the posterior surface of the petrous portion of the temporal bone. It transmits a small vein, and contains a tubular prolongation (ductus endolymphaticus) which, derived from the saccule and utricle, in a manner to be described later, ends in a cul-de-sac. On the upper wall or roof is a transverse oval depression, fovea semi-elliptica, separated from the fovea hem-
ispheralica by the pyramidal eminence already mentioned. Behind, the semicircular canals open into the vestibule by five orifices. In front is a large oval opening which communicates with the scala vestibuli of the cochlea by a single orifice, *apertura scala vestibuli cochlear*.

The **Semicircular canals** are three bony canals situated above and behind the vestibule. They are of unequal length, compressed from side to side, and describe the greater part of a circle. They measure about one-twentieth of an inch in diameter, and each presents a dilatation at one end, called the *ampulla*, which measures more than twice the diameter of the tube. These canals open into the vestibule by five orifices, one of the apertures being common to two of the canals.

The **superior semicircular canal** is vertical in direction, and stretches across the petrous portion of the temporal bone, at right angles to its posterior surface; its arch forms a round projection on the anterior surface of the petrous bone. It describes about two-thirds of a circle. Its outer extremity, which is ampullated, commences by a distinct orifice in the upper part of the vestibule; the opposite end of the canal, which is not dilated, joins with the corresponding part of the posterior canal, and opens by a common orifice with it in the back part of the vestibule.

The **posterior semicircular canal**, also vertical in direction, is directed backward, nearly parallel to the posterior surface of the petrous bone; it is the longest of the three: its ampullated end commences at the lower and back part of the vestibule, its opposite end joining to form the common canal already mentioned.

The **external or horizontal canal** is the shortest of the three, its arch being directed outward and backward; thus each semicircular canal stands at right angles to the other two. Its ampullated end corresponds to the upper and outer angle of the vestibule, just above the fenestra ovalis; its opposite end opens by a distinct orifice at the upper and back part of the vestibule.

The **Cochlea** bears some resemblance to a common snail-shell: it forms the anterior part of the labyrinth, is conical in form, and placed almost horizontally in front of the vestibule; its apex is directed forward and outward toward the upper and front part of the inner wall of the tympanum; its base corresponds with the anterior depression at the bottom of the internal auditory meatus, and is perforated by numerous apertures for the passage of the cochlear branch of the
auditory nerve. It measures about a quarter of an inch in length, and its breadth toward the base is about the same. It consists of a conical-shaped central axis, the modiolus or columnella; of a canal wound spirally round the axis for two turns and a half, from the base to the apex; and of a delicate lamina (the lamina spiralis) contained within the canal, which follows its windings and partially subdivides it into two.

The central axis, or modiolus, is conical in form, and extends from the base to the apex of the cochlea. Its base is broad, corresponds with the first turn of the cochlea, and is perforated by numerous orifices, which transmit filaments of the cochlear branch of the auditory nerve; the axis diminishes rapidly in size in the second coil, and terminates within the last half-coil, or cupola, in an expanded delicate, bony lamella, which resembles the half of a funnel divided longitudinally, and is called the infundibulum; the broad part of this funnel is directed toward the summit of the cochlea, and blends with the cupola or last half-turn of the spiral canal of the cochlea. At this point the two larger scale of the cochlea, the scala tympani and scala vestibuli, communicate by an opening called the helicotrema. The outer surface of the modiolus forms part of the wall of the spiral canal, and is dense in structure; but its centre is channelled, as far as the last half-coil, by numerous branching canals, which transmit nervous filaments in regular succession into the canal of the cochlea or on to the surface of the lamina spiralis. One of these, larger than the rest, occupies the centre of the modiolus, and is named the candis centralis modioli; it extends from the base to the extremity of the modiolus, and transmits a small nerve and artery (arteria centralis modioli).

The spiral canal (Fig. 548) takes two turns and a half round the modiolus. It is about an inch and a half in length, measured along its outer wall, and diminishes gradually in size from the base to the summit, where it terminates in a cul-de-sac, the cupola, which forms the apex of the cochlea. The commencement of this canal is about the tenth of an inch in diameter; it diverges from the modiolus toward the tympanum and vestibule and presents three openings. One, the fenestra rotunda, communicates with the tympanum; in the recent state this aperture is closed by a membrane, the membrana tympani secundaria. Another aperture, of an oval form, enters the vestibule. The third is the aperture of the aqueductus cochler, leading to a minute funnel-shaped canal, which opens on the basilar surface of the petrous bone and transmits a small vein.

The interior of the spiral canal (Fig. 549) is partially divided into two, in the dry state, by a thin bony plate, the lamina spiralis, which consists of two thin lamellae of bone, between which are numerous canals for the passage of nerve-fibres. This lamina projects from the modiolus into the canal, but does not reach more than halfway toward the outer wall of the tube. From its extremity a thin membrane extends to the outer wall, and completes the division of the canal into an upper compartment, the scala vestibuli, and a lower one, the scala tympani.
By a second membrane a portion of the upper of these two canals is cut off from the rest, constituting the scala media. The lamina spiralis ends above in a hook-shaped process (hamulus) which partly bounds the helicotrema. At the point where the osseous lamina is attached to the modiolus is a small canal, which winds round the modiolus, and was denominated by Rosenthal the canalis spiralis modioli; it is occupied by a swelling of the cochlear nerve, the ganglion spirale, in which ganglion-cells are found, and from which the nerves pass to the osseous lamina and organ of Corti. The scala media belongs to the membranous labyrinth.

The osseous lamina, as above stated, extends only part of the distance between the modiolus and the outer bony wall of the cochlea. Near its outer end the periosteum on the upper or vestibular surface of the lamina swells up into an elevation which is called the limbus laminae spiralis ("denticulate lamina" of Todd and Bowman). The lamina spiralis terminates in a grooved extremity, the sulcus spiralis, which presents the form of the letter C: the upper part of the letter, being formed by the overhanging extremity of the limbus, is named the labium vestibulare; the lower part, prolonged and tapering, is called the labium tympanicum (Fig. 550). From the labium tympanicum a thin membrane extends over to the bony wall of the cochlea, completing the scala tympani. This membrane is called the membrana basilaris. At its outer attachment it swells out so as to form a thick triangular structure, which was regarded as a muscle by Todd and Bowman (cochlearis), but is now recognized as ligamentous—the ligamentum spirale. Between the labium vestibulare and the attachment of the membrane of Reissner, presently to be described, a very delicate membrane extends over to the outer wall of the cochlea, running nearly parallel to the membrana basilaris. It was described by Corti, and covers over the organ which is called after his name, and is therefore called membrane of Corti, or membrana tectoria. Farther inward, near the commencement of the limbus laminae spiralis, another delicate membrane, the membrane of Reissner, is attached to the vestibular surface of the periosteum of the osseous lamina and stretches across to the outer wall of the cochlea. The canal which lies below the osseous lamina and membrana basilaris is the scala tympani; that which is bounded by the osseous lamina and membrane of Reissner, the scala vestibuli; while the space between the membrane of Reissner and membrana basilaris is generally described as the Scala media, Canalis membranaceae, or Canalis cochlea, and this is the nomenclature which will be used here. Others, however, apply the name canalis cochlea only to the canal
lying between the membrane of Reissner and the membrana tectoria, which contains no object for description, while the space lying between the membrana tectoria and membrana basilaris is described by itself as a fourth canal—the ductus cochlearis or ductus auditorius. The latter is the space in which the organ of Corti is contained. This organ (Fig. 550) is situated upon the membrana basilaris, and appears at first sight as a papilla, winding spirally with the turns of this membrane throughout the whole length of the cochlea, from which circumstance it has been designated the papilla spiralis. More accurately viewed, it is seen to be composed of a remarkable arrangement of cells which may be likened to the keyboard of a pianoforte. Of these cells, the two central ones are rod-like bodies, and are called the inner and outer rods of Corti. They are placed erect on the basilar membrane at some little distance from each other, the space between them being denominated the zona areuata; they are inclined toward each other, so as to meet at their opposite extremities and form a series of arches roofing over the zona areuata, thus forming a minute tunnel between them and the basilar membrane, which ascends spirally through the whole length of the cochlea. They are estimated at over three thousand in number.

The inner rods, which are more numerous than the outer ones, rest on the basilar membrane, close to the labium tympanicum; they project obliquely forward and outward, and terminate above in expanded extremities, which resemble in shape the upper end of the ulna, with its sigmoid cavity, coronoid and olecranon processes. On the outer side of the rod, in the angle formed between it and the basilar membrane, is a protoplasmic cell, whilst on the inner side is a row of epithelial cells surmounted by a brush of fine, stiff, hair-like processes, these cells being continuous with the cubical cells lining the sulcus spiralis.

The outer rods also rest by a broad foot on the basilar membrane; they incline forward and inward, and their upper extremity resembles the head and bill of a swan, the head fitting into the concavity—the analogue of the sigmoid cavity—of one or more of the internal rods, and the bill resting against the phalanges of the lamina reticularis, presently to be described.

In the head of these outer rods is an oval portion, where the fibres of which the rod appears to be composed are deficient, and which stains more deeply with carmine than the rest of the rod. This is supposed to represent the nucleus of the cell from which the rod was originally developed. At the base of the rod, on its internal side—that is to say, in the angle formed by the rod with the basilar membrane—is a similar protoplasmic cell to that found on the outer side of the base of the inner rod, whilst external to the outer rod are three or four successive

\[1\] In reading the older descriptions of the organ of hearing the student must bear in mind that the membranes bounding the ductus auditorius, together with the organ contained between them, were described together as the "lamina spiralis membranacea," while the membrane of Reissner was not recognized, the parts being, in fact, as shown in the second turn of the cochlea on the right hand of Fig. 549.

\[2\] Corti's original paper is in the Zeitschrift f. Wissen. Zool., iii. 108.
rows of epithelial cells, more elongated than those found on the internal side of the inner rod, but, like them, furnished with minute hairs or cilia. These are termed the outer hair-cells, in contradistinction to the inner set, which are termed the inner hair-cells. They are attached by their bases to the basilar membrane, whilst from the opposite extremity a brush of hairs or cilia projects through the reticular membrane. They are continuous externally with the cubical cells on the lateral part of the basilar membrane.

The reticular lamina or membrane of Kölliker is a delicate framework perforated by rounded holes. It extends from the inner rods of Corti to the external row of the outer hair-cells, and is formed by several rows of "minute fiddle-shaped cuticular structures," called phalanges, between which are holes for the projection of the cilia of the outer hair-cells.

Covering over these structures, but not touching them, is the membrana tectoria, or membrane of Corti, which is attached to the vestibular surface of the lamina spiralis close to the attachment of the membrane of Reissner; it courses over the denticulate lamina, and, passing outward parallel to the basilar membrane, is blended with the ligamentum spirale on the outer wall of the spiral canal. 1

The inner surface of the osseous labyrinth is lined by an exceedingly thin fibro-serous membrane, analogous to a periosteum from its close adhesion to the inner surfaces of these cavities, and performing the office of a serous membrane by its free surface. It lines the vestibule, and from this cavity is continued into the semicircular canals and the scala vestibuli of the cochlea, and through the helicotrema into the scala tympani. This membrane is continued across the fenestrae ovalis and rotunda, and consequently has no communication with the lining membrane of the tympanum. Its attached surface is rough and fibrous, and closely adherent to the bone; its free surface is smooth and pale, covered with a layer of epithelium, and secretes a thin, limpid fluid, the aqua labyrinthi, liquor Cotunnii, or perilymph (Blainville).

The Membranous Labyrinth.

The membranous labyrinth (Fig. 551) is a closed sac, containing fluid, on the walls of which the ramifications of the auditory nerve are distributed. It has the same general form as the cochlea, vestibule, and semicircular canals in which it is enclosed, but is considerably smaller, and the vestibular and canalicular portions are more or less surrounded by the perilymph.

The scala media, already described in connection with the cochlea, is closed above and below. The upper blind extremity is attached to the cupola at the upper part of the helicotrema; the lower end fits into the angle at the commencement of the osseous lamina on the floor of the vestibule. Near this blind extremity the scala media receives the canalis reuniens (Fig. 551), a very delicate canal by which the ductus cochlearis is brought into continuity with the sacculus.

The vestibular portion consists of two sacs, the utricle and the saccule.

The utricle is the larger of the two, of an oblong form, compressed laterally, and occupies the upper and back part of the vestibule, lying in contact with the fovea semi-elliptica. Numerous filaments of the auditory nerve are distributed on the wall of this sac, and its cavity communicates behind with the membranous semicircular canals by five orifices. It also sends off a minute canal into the aqueductus vestibuli, which unites with the ductus endolymphaticus, a similar but somewhat larger tubular prolongation from the saccule.

The saccule is the smaller of the two vestibular sacs; it is globular in form, lies in the fovea hemispherica near the opening of the vestibular scala of the cochlea, and receives numerous nervous filaments which enter from the bottom of the depression in which it is contained. Its cavity communicates with that of the scala media by means of the canalis reuniens and with that of the utricle in the manner just mentioned.

1 In Fig. 550 only the inner half of the membrane is represented.
The membranous semicircular canals are about one-third the diameter of the osseous canals, but in number, shape, and general form they are precisely similar: they are hollow, and open by five orifices into the utricle, one opening being common to two canals. Their ampullae are thicker than the rest of the tubes, and nearly fill the cavities in which they are contained.

Numerous fibrous bands stretch across between the membranous and bony labyrinths. These fibrous bands convey the blood-vessels and nervous filaments distributed to the utricle, to the saccule, and to the ampulla of each canal.

Structure.—The wall of the membranous labyrinth is semi-transparent, and consists of three layers. The outer layer is a loose and flocculent structure, apparently composed of ordinary fibrous tissue, containing blood-vessels and numerous pigment-cells analogous to those in the pigment-coat of the retina. The middle layer, thicker and more transparent, bears some resemblance to the hyaloid membrane, but it presents on its internal surface numerous papilliform projections, and on the addition of acetic acid presents an appearance of longitudinal fibrillation and elongated nuclei. The inner layer is formed of polygonal nucleated epithelial cells, which secrete the endolymp.

The endolymph (liquor Scarpe) is a limpid serous fluid which fills the membranous labyrinth; in composition it closely resembles the perilymph.

The otoliths are two small rounded bodies consisting of a mass of minute crystalline grains of carbonate of lime, held together in a mesh of delicate fibrous tissue, and contained in the walls of the utricle and saccule, opposite the distribution of nerves. A calcareous material is also, according to Bowman, sparingly scattered in the cells lining the ampulla of each semicircular canal.

The arteries of the labyrinth are—the internal auditory, from the basilar; the stylo-mastoid, from the posterior auricular; and, occasionally, branches from the occipital. The internal auditory divides at the bottom of the internal meatus into two branches, cochlear and vestibular.

The cochlear branch subdivides into from twelve to fourteen twigs, which traverse the canals in the modiolus, and are distributed, in the form of a capillary network, in the substance of the lamina spiralis.

The vestibular branches accompany the nerves, and are distributed, in the form of a minute capillary network, in the substance of the membranous labyrinth.

The veins (auditory) of the vestibule and semicircular canals accompany the arteries, and, receiving those of the cochlea at the base of the modiolus, terminate in the superior petrosal sinus.

The auditory nerve, the special nerve of the sense of hearing, divides, at the

---

Fig. 551.—The membranous labyrinth. (Enlarged.)
bottom of the internal auditory meatus, into two branches, the cochlear and vestibular. The trunk of the nerve, as well as the branches, contains numerous ganglion-cells with caudate prolongations.

The vestibular nerve, the posterior of the two, divides into three branches—superior, middle, and inferior.

The superior vestibular branch, the largest, divides into numerous filaments, which pass through minute openings at the upper and back part of the cut-de-sac at the bottom of the meatus, and, entering the vestibule, are distributed to the utricle and to the ampulla of the external and superior semicircular canals.

The middle vestibular branch consists of numerous filaments, which enter the vestibule by a smaller cluster of foramina placed below those above mentioned, and which correspond to the bottom of the fovea hemispherica; they are distributed to the saccule.

The inferior and smallest branch passes backward in a canal behind the foramina for the nerves of the saccule, and is distributed to the ampulla of the posterior semicircular canal.

The nervous filaments enter the ampullary enlargements at a deep depression seen on their external surface, with a corresponding elevation when seen from within; the nerve-fibres ending in loops and in free extremities. In the utricle and saccule the nerve-fibres spread out, some blending with the calcareous matter; others, radiating on the inner surface of the wall of each cavity, become blended with a layer of nucleated cells and terminate in a thin fibrous film.

The cochlear nerve divides into numerous filaments at the base of the modiolus, which ascend along its canals, and then, bending outward at right angles, pass between the plates of the bony lamina spiralis, close to its tympanic surface. Between the plates of the spiral lamina the nerves form a plexus which contains ganglion cells forming the ganglion spirale. From this ganglion delicate filaments pass between the layers of the osseous lamina to the saccule spiralis and pass outward to the organ of Corti. Their exact termination is uncertain. Waldeyer describes them as collected into two groups, one ending in the outer and the other in the inner hair-cells.

The bottom of the internal auditory meatus, known as the lamina cribrosa, is subdivided by a horizontal ridge, the crista falciformis, into a superior and an inferior fossa. In the superior fossa is seen anteriorly the foramen faciale or orifice of the aqueductus Fallopii; and posteriorly is a group of foramina, area cribrosa superior, for the nerve-filaments to the utricle, superior and external semicircular canals (superior vestibular branch). In the inferior fossa are: (1) a group of foramina, area cribrosa media, for the filaments to the saccule (middle vestibular branch); (2) posteriorly, the foramen singulare, for the nerve to the posterior semicircular canal (inferior vestibular branch); (3) antero-inferiorly, the foramina for the filaments of the cochlear branch, grouped in a spiral, tractus spiralis foraminulentus, and at the end of the spiral is the foramen centrale cochlearis or orifice of the central canal of the modiolus.

Surgical Anatomy.—Malformations, such as imperfect development of the external parts, absence of the meatus, or supernumerary auricles, are occasionally met with. Or the pinna may present a congenital fistula which is due to defective closure of the first visceral eleft, or rather of that portion of it which is not concerned in the formation of the Eustachian tube, tympanum, and meatus. The skin of the auricle is thin and richly supplied with blood, but in spite of this it is frequently the seat of frost-bite, due to the fact that it is much exposed to cold, and lacks the usual covering of subcutaneous fat found in most other parts of the body. A collection of blood is sometimes found between the cartilage and perichondrium (hematoma auris), usually the result of traumaism, but not necessarily due to this cause. It is said to occur most frequently in the ears of the insane. Keloid sometimes grows in the auricle around the puncture made for earrings, and epithelium occasionally affects this part. Deposits of urate of soda are often met with in the pinna in gouty subjects.

The external auditory meatus can be most satisfactorily examined by light reflected down a funnel-shaped speculum; by gently moving the latter in different directions the whole of the canal and membrana tympani can be brought into view. The points to be noted
are, the presence of wax or foreign bodies, the size of the canal, and the condition of the membrana tympani. The accumulation of wax is often the cause of deafness, and may give rise to very serious consequences, causing ulceration of the membrane and even absorption of the bony wall of the canal. Foreign bodies are not infrequently introduced into the ear by children, and, when situated in the first portion of the canal, may be removed with tolerable facility by means of a minute hook or loop of fine wire, with reflected light; but when they have slipped beyond the narrow middle part of the meatus, their removal is in no wise easy, and attempts to effect it, in inexperienced hands, may be followed by destruction of the membrana tympani and possibly the contents of the tympanum. The closure of the external auditory canal may be narrowed by inflammation of its lining membrane, running on to suppuration; by periostitis; by polypi, sebaceous tumors, and exostoses. The membrana tympani, when seen in a healthy ear, reflects light strongly, and, owing to its peculiar curvature, presents a bright spot of triangular shape at its lower and anterior portion. From the apex of this, proceeding upward and slightly forward, is a white streak formed by the handle of the malleus, while at the upper and middle part of the membrane may be seen a slight projection, caused by the short process of the malleus. In disease alterations in color, lustre, curvature or inclination, and perforation must be noted. Such perforations may be caused by a blow or a loud report or by a wound.

The upper wall of the meatus is separated from the cranial cavity by a thin plate of bone; the anterior wall is separated from the temporo-massary joint and parotid gland by the bone forming the glenoid fossa; and the posterior wall is in relation with the mastoid cells; hence inflammation of the external auditory meatus may readily extend to the membranes of the brain, to the temporo-massary joint, or to the mastoid cells; and, in addition to this, blows on the chin may cause fracture of the wall of the meatus.

The nerves supplying the meatus are the auricular branch of the pneumogastric, the auriculo-temporal, and the auricularis magnus. The connections of these nerves explain the fact of the occurrence, in cases of any irritation of the meatus, of constant coughing and sneezing from irritation of the pneumogastric, or of yawning from irritation of the auriculo-temporal. No doubt also the association of caracne with toothache in cancer of the tongue is due to implication of the same nerve, a branch of the fifth, which supplies also the teeth and the tongue. The vessels of the meatus and membrana tympani are derived from the posterior auricular, temporal, and internal massary arteries. The upper half of the membrana tympani is much more richly supplied with blood than the lower half. For this reason, and also to avoid the chorda tympani nerve and ossicles, incisions through the membrane should be made at the lower and posterior part.

The principal point in connection with the surgical anatomy of the tympanum is its relations to other parts. Its roof is formed by a thin plate of bone, which, with the dura mater, is all that separates it from the temporo-sphenoidal lobe of the brain. Its floor is immediately above the jugular fossa behind and the carotid canal in front. Its posterior wall presents the openings of the mastoid cells. On its anterior wall is the opening of the Eustachian tube. Thus it follows that in disease of the middle ear we may get subdural abscess, septic meningitis, or abscess of the cerebrum or cerebellum from extension of the inflammation through the bony roof; thrombosis of the lateral sinuses, with or without pyaemia, by extension through the floor; or mastoid abscess by extension backward. In addition to this, we may get fatal hemorrhage from the internal carotid in destructive changes of the middle ear; and in throat disease we may get the inflammation extending up the Eustachian tube to the middle ear. The Eustachian tube is accessible from the nose. If the nose and mouth be closed and an attempt made to expire air, a sense of pressure with dulness of hearing is produced in both ears, from the air finding its way up the Eustachian tube and bulging out the membrana tympani. During the act of swallowing the pharyngeal orifice of the tube, which is normally closed, is opened, probably by the action of the Tensor tympani. This fact was employed by Politzer in devising an easy method of inflating the tube. The nozzle of an India-rubber syringe is inserted into the nostril; the patient takes a mouthful of water and holds it in his mouth; both nostrils are closed with the finger and thumb to prevent the escape of air, and the patient is then requested to swallow; as he does so the air is forced out of the syringe into his nose, and is driven into the Eustachian tube, which is now open. The impact of the air against the membrana tympani can be heard, if the membrane is sound, by means of a piece of India-rubber tubing, one end of which is inserted into the meatus of the patient's ear, the other into that of the surgeon. The direct examination of the Eustachian tube is made by the Eustachian catheter. This is passed along the floor of the nostril, with the curve downward, to the posterior wall of the pharynx. When this is felt, the catheter is to be withdrawn about half an inch, and the point rotated outward through a quarter of a circle, and pushed again slightly backward, when it will enter the orifice of the tube, and will be found to be caught, and air forced into the catheter will be heard impinging on the tympanic membrane if the ears of the patient and surgeon are connected by an India-rubber tube.
THE ORGANS OF DIGESTION.

The Apparatus for the Digestion of the Food consists of the alimentary canal and of certain accessory organs.

The alimentary canal is a musculo-membranous tube, about thirty feet in length, extending from the mouth to the anus, and lined throughout its entire extent by mucous membrane. It has received different names in the various parts of its course: at its commencement, the mouth, we find provision made for the mechanical division of the food (mastication), and for its admixture with a fluid secreted by the salivary glands (insalivation); beyond this are the organs of deglutition, the pharynx and the œsophagus, which convey the food into that part of the alimentary canal (the stomach) in which the principal chemical changes occur, and in which the reduction and solution of the food take place; in the small intestines the nutritive principles of the food (the chyle) are separated, by its admixture with the bile and pancreatic fluid, from that portion which passes into the large intestine, most of which is expelled from the system.

Spleen.

The mouth (oral or buccal cavity) (Fig. 552) is the vestibule to the alimentary canal. It is a nearly oval-shaped cavity, bounded in front by the lips, upon the sides by the cheeks, behind by the soft palate and fauces. The upper and lower dental arches, together with their alvolar processes, subdivide the general cavity into a lingual and a buccal cavity. The latter has as its inner wall the external faces of the teeth and gums of both jaws; its external wall is formed by the lips and cheeks. The lingual cavity is bounded anteriorly and laterally by the lingual surfaces of both dental arches; above, by the hard and the soft palates; below, by the floor of the mouth and the tongue.

The mucous membrane lining the mouth is continuous with the integument at the free margin of the lips and with the mucous lining of the fauces behind; it is of a rose-pink tinge during life, and very thick where it covers the hard parts bounding the cavity. It is covered by stratified epithelium.

The lips are two fleshy folds which surround the orifice of the mouth, formed externally of integument and internally of mucous membrane, between which are found the Orbicularis oris muscle, the coronary vessels, some nerves, areolar tissue, and fat, and numerous small labial glands. The inner surface of each lip is con-
nected in the middle line to the gum of the corresponding jaw by a fold of mucous membrane, the *frenum labii superioris* and *inferioris*—the former being the larger of the two.

The *labial glands* are situated between the mucous membrane and the Orbicularis oris round the orifice of the mouth. They are rounded in form, about the size of small peas, their ducts opening by small orifices upon the mucous membrane. In structure they resemble the salivary glands.

The *cheeks* form the sides of the face and are continuous in front with the lips. They are composed externally of integument, internally of mucous membrane, and between the two of a muscular stratum, besides a large quantity of fat, areolar tissue, vessels, nerves, and buccal glands.

The *mucous membrane* lining the cheek is reflected above and below upon the gums, where its color becomes lighter; it is continuous behind with the lining mem-

---

---

brane of the soft palate. Opposite the second molar tooth of the upper jaw is a papilla, the summit of which presents the aperture of the duct of the parotid gland. The principal muscle of the cheek is the Buccinator, but numerous other muscles enter into its formation—viz. the Zygomatici, Risorius Santorini, and Platysma myoides.

The *buccal glands* are placed between the mucous membrane and Buccinator muscle; they are similar in structure to the labial glands, but smaller. Two or three of larger size than the rest are placed between the Masseter and Buccinator muscles; their ducts open into the mouth opposite the last molar tooth. They are called *molar glands*.

The *gums* are composed of a dense fibrous tissue closely connected to the
THE ORGANS OF DIGESTION.

periosteum of the alveolar processes and surrounding the necks of the teeth. They are covered by smooth and vascular mucous membrane, which is remarkable for its limited sensibility. Around the necks of the teeth this membrane presents numerous fine papillae. The deep fibrous layer is continuous with the periosteum lining the alveoli, (the pericementum).

THE TEETH.

The human subject is provided with two sets of teeth, which make their appearance at different periods of life. The first set appear in childhood, and are called the temporary, deciduous, or milk teeth. The second set are named permanent.

The temporary teeth are twenty in number—four incisors, two canine, and four molars, in each jaw (Fig. 553).

The permanent teeth are thirty-two in number—four incisors (two central and two lateral), two canines, four bicuspids, and six molars in each jaw (Fig. 554).

General Characters.—Each tooth consists of three portions: the crown, or body, projecting above the gum; the root, or fang, entirely concealed within the alveolus; and the neck, the constricted portion, between the root and crown.

The surfaces of a tooth are named thus: that which looks toward the lips is the labial; that toward the tongue is the lingual; that toward the mesial line, proximal; that away from the same, distal; that toward the cheek, the buccal surface. This applies to the roots as well as to the crowns of teeth.

The roots of the teeth are firmly implanted within the alveoli (Fig. 558); these depressions are lined with periosteum (the pericementum) which is reflected on to the tooth at the point of the root and covers it as far as the neck. At the margin of the alveolus the periosteum becomes continuous with the fibrous structure of the gums.

Permanent Teeth (Figs. 555 and 556).

The incisors, or cutting teeth, are so named from their presenting a sharp cutting edge, adapted for incising the food. They are eight in number, and comprise the four front teeth in each jaw.
The crown is directed almost vertically and is spade-like in form; it has the form of a truncated cone whose top has been compressed into a sharp horizontal cutting edge. Before being subjected to attrition this edge presents three small elevations. The labial surface is convex, and marked by three longitudinal ridges extending from the edge tubercles toward the neck of the tooth. The lingual surface is concave, and is marked by two marginal ridges extending from an encircling ridge at the neck to the angles of the cutting edge of the tooth. The ridge at the neck is termed the cingulum or basal ridge.

The mesial and distal surfaces are triangular, the apex of the triangle at the cutting edge.

The neck of the tooth is constricted.

The root is long, single, and has the form of a transversely flattened cone, thicker before than behind. The root may be curved.

The incisors of the upper jaw are altogether larger and stronger than those of the lower jaw, the central incisors being larger and flatter than the laterals. They are directed obliquely downward and forward.

The incisors of the lower jaw are smaller and flatter than the upper, and the elevations upon their lingual faces are not marked. The two central are smaller than the two lateral incisors, being the smallest of all the teeth. The roots of these teeth are flattened laterally.

The canine teeth (cuspidae) are four in number, two in the upper, two in the lower jaw—one being placed distal to each lateral incisor. They are larger and stronger than the incisors, especially in the roots, which are deeply implanted and cause well-marked prominence of the process at the places of insertion.

The crown is large, of spear-head, form and its very convex labial surface is marked by three longitudinal ridges. The concave labial surface is also marked by three ridges which unite at a basal ridge. The point or cusp is longer than in the other teeth, and is the point of division between a short mesial and a long distal cutting edge.

The root is oval or elliptical in transverse section, and is longer and more prominent than the roots of the incisors.

The upper canines or cuspids (vulgarly called the eye teeth) are larger and longer than the two lower, and in occlusion are distal to them to the extent of half the width of the crown.

The lower canines (vulgarly called the stomach teeth) have the general form of the upper cuspids, but their lingual surfaces are much more flattened, owing to the absence of the elevations marking the upper. Their roots are more flattened and may be bifid at their apices.

The bicuspid teeth (premolars) are eight in number, four in each jaw; they are placed distal to the cuspid teeth, two upon each side. They are double cuspids in form.

The crown is surmounted by two cusps, one buccal and one lingual, separated by a groove, the buccal being more prominent and larger than the lingual. The lower bicuspid are not truly bicuspid, the first having but a primitive lingual cusp, the second having the lingual cusp divided into two sections—i.e., it is usually tricuspid.

The necks of the teeth are oval; the roots are laterally compressed, that of the
first upper bicuspid being frequently bifid. The first upper bicuspid is usually the largest of the series.

The molar teeth (*multicuspidati*; or grinders) are the largest teeth of the denture. They are adapted by their forms for the crushing and grinding of the food. They are twelve in number, six in each jaw, three being placed posterior to each second bicuspid.

The crowns are cuboidal in form, are convex buccally and lingually; they are flattened mesially and distally. They are formed by the fusion of three primitive cusps in the upper and four in the lower. To these are added in the first and second upper molars a disto-lingual tubercle, and in the first and third molars of the lower jaw a disto-buccal tubercle. The unions of the primitive forms are marked by sulci. The necks of these teeth are large and rhomboidal in form.

The roots of the upper molars are three in number—one large lingual and two smaller buccal roots. In the lower, two roots are found, a mesial and a distal, each of which is much flattened from before backward.

The first molar teeth are the largest of the dental series: they have four cusps on the upper and five in the lower—three buccal and two lingual.

The second molars are smaller; the crown of the upper is compressed until the disto-lingual cusp is reduced. The crowns of the lower are almost rectangular, with a cusp at each angle.

The third molars are called the wisdom teeth (*dentes sapientiae*) from their late eruption: they have three cusps upon the upper and five upon the lower. The three roots of the upper are frequently fused together, forming a grooved cone, which is usually curved backward. The roots of the lower, two in number, are compressed together and curve backward.

**Temporary Teeth** (Figs. 553 and 557).

The temporary or milk teeth are smaller, but resemble in form those of the permanent set. The neck is more marked, owing to the greater degree of convexity of the labial and lingual surfaces of the crown. The hinder of the two temporary molars is the largest of all the deciduous teeth, and is succeeded by the second bicuspid. The first upper molar has only three cusps—two labial, one lingual; the second upper molar has four cusps. The first lower molar has four cusps; the second lower molar has five. The roots of the temporary molar teeth are smaller and more diverging than those of the permanent set, but in other respects bear a strong resemblance to them.

**Arrangement of the Teeth.**

The human teeth are arranged in two parabolic arches, the upper arch being larger, its teeth overlapping the lower. The average distance between the centres of the condyles of the inferior maxillary bones is about four inches, which is also the distance from either of these points to the line of junction between the lower incisor teeth. Whether the jaw be large or small, the equilateral triangle indicated is included in it; the range of size is between \(\frac{31}{2}''\) and \(\frac{41}{2}''\).

Owing to the smaller sizes of the lower incisors, the teeth of the lower jaw are each one half a tooth in advance of its upper fellow, so that each tooth of the dental series has two antagonists, with the exception of the lower central incisors and upper third molars (Figs. 558, 559).

The grinding faces of the upper bicuspids and molars curve progressively upward and point outward, the first molar being at the lowest point of the curve,

---

1 After Dr. W. G. A. Bonwill.
the third molar at the highest. The curve of the lower dental arch is the reverse, the first molar at its deepest part, the third molar at its extremity. The greater the depth to which the upper incisors overlap the lower, the more marked this curve and the more pointed are the cusps of the grinding teeth.

The movement of the human mandible is forward and downward, the resultant of these directions being an oblique line, upon an average 35° from the horizontal plane. When the lower jaw is advanced until the cutting edges of the incisors are in contact, the jaws are separated, but as the highest point of the lower arch, its third molar advances, it meets and rests upon a high point, second molar of the upper arch, and thus undue strain of the incisors is obviated.

In the lateral movements of the mandible but one side is in effective action at one time; the oblique positions of the cusps of the opposite teeth are such that when either side is in action the other is balanced at two or more points.

1 W. E. Walker, Dental Cosmos, 1896.
There is an anatomical correspondence between the forms and arrangement of the teeth, the form of the condyle of the inferior maxilla, and the muscular arrangement. Individuals who have teeth with long cusps have the head of the bone much rounded from before behind, and have a preponderance of the direct over the oblique muscles of mastication, and vice versa; teeth with short or no cusps are associated with a flattened condyle and strong oblique muscles.

Very great aberrations in the dental arrangement are frequently followed by accommodative changes in the heads of the inferior maxilla.

Structure of the Teeth.

The Dental Pulp.—A longitudinal section of a tooth will show the presence of a central chamber having the general form of the crown of the tooth. Processes of the chamber pass from its body, one for each root and down each root, and open at the apex by a minute orifice, the apical foramen. This cavity is known as the pulp-chamber, the minute canals the pulp-canals. The cavity contains a soft, vascular, and sensitive organ called the dental pulp. It is made up of myxomatous tissues, and contains numerous blood-vessels and nerves, which enter by way of the apical foramina. It does not possess lymphatics. The periphery of the pulp is bounded by a layer of cells arranged like columnar epithelium, each cell sending one or more branched processes through the basic substance of the dentine. These are the dentine-forming cells, the odontoblasts of Waldeyer. The blood-vessels break up into innumerable capillary loops which lie beneath the layer of odontoblasts. The nerve-fibrils break up into numberless non-medullary filaments, which spread out beneath the odontoblasts, and probably send terminal filaments to the extreme periphery of the pulp outside the odontoblasts.

The matrix cells and their processes are irregularly arranged in the body of the pulp, but in the canal portion the fibrillae are in the direction of the axis of the root.

The section will exhibit three hard tissues in a tooth, one forming the greater mass of the tooth; hence its name dentine (the ivory). The dentine upon the crown is sheathed by a layer called the enamel; the dentine of the root is enclosed
STRUCTURE OF THE TEETH.

in a distinct tissue, the cementum or crista petrosa; both cementum and enamel are thinnest at the neck and thickest upon their distal portions.

The solid portion of the tooth consists of three distinct structures—viz. the proper dental substance, which forms the larger portion of the tooth, the ivory or dentine; a layer which covers the exposed part of the crown, the enamel; and a thin layer, which is disposed on the surface of the fang, the cement or crista petrosa.

The ivory, or dentine (Fig. 561), forms the principal mass of a tooth; in its central part is the cavity enclosing the pulp. It is a modification of osseous tissue, from which it differs, however, in structure. On microscopic examination it is seen to consist of a number of minute wavy and branching tubes having distinct parietes. They are called the dentinal tubuli, and are imbedded in a dense homogeneous substance, the intertubular tissue.

The dentinal tubuli (Fig. 562) are placed parallel with one another, and open at their inner ends into the pulp-cavity. In their course to the periphery they present two or three curves, and are twisted on themselves in a spiral direction. The direction of these tubes varies: they are vertical in the upper portion of the crown, oblique in the neck and upper part of the root, and toward the lower part of the root they are inclined downward. The tubuli, at their commencement, are about \( \frac{\sqrt{2}}{4} \) of an inch in diameter; in their course they divide and subdivide dichotomously, so as to give to the cut surface of the dentine a striated appearance. From the sides of the tubes, especially in the root, ramifications of extreme minuteness are given off, which join together in loops in the intertubular substance, or terminate in small dilatations, from which branches are given off. Near the periphery of the dentine the finer ramifications of the tubuli terminate in a layer of irregular branched spaces which communicate with each other. These are called the interglobular spaces of Czermak, or the granular layer of Tomes (Fig. 562, J). The dentinal tubuli have comparatively thick walls, and contain slender cylindrical prolongations from the processes of the cells of the pulp-tissue already mentioned, and first described by Mr. Tomes and named Tomes's fibres or dentinal fibres. These dentinal fibres are analogous to the soft contents of the canaliculi of bone. Between Tomes's fibres and the ivory around the canals there is a tissue which is markedly resistant to the action of acids—the dentinal sheath of Neumann.

The intertubular substance or tissue is translucent, and contains the chief part of the earthy matter of the dentine. After the earthy matter has been removed by steeping a tooth in weak acid the animal basis remaining may be torn into laminae which run parallel with the pulp-cavity across the direction of the tubes. These laminae show the method of growth to be by deposition of successive strata of dentine. Fibrils have been found in the matrix of the intertubular substance, and are probably continuous with the dentinal fibres of Tomes. In a dry tooth a
section of dentine often displays a series of lines—the *incremental lines of Salter*—which are parallel with the laminae above mentioned. These lines are caused by two facts: (1) The imperfect calcification of the dentinal laminae immediately adjacent to the line; (2) The drying process, which reveals these defects in the calcification. These lines are wide or narrow according to the number of laminae involved, and along their course, in consequence of the imperfection in the calcifying process, little irregular cavities are left, which are the *interglobular spaces* already referred to. They have received their name from the fact that they are surrounded by minute nodules or globules of dentine. Other curved lines may be seen parallel to the surface. These are the *lines of Schreger*, and are due to the optical effect of simultaneous curvature of the dentinal tubules.

**Chemical Composition.**—According to Berzelius and Bibra, dentine consists of 28 parts of animal and 72 of earthy matter. The animal matter is resolvable by boiling into gelatin. The earthy matter consists of phosphate and carbonate with calcium, with a trace of fluoride of calcium, phosphate of magnesia, and other salts.

The *enamel* is the hardest and most compact part of a tooth, and forms a thin crust over the exposed part of the crown as far as the commencement of the root. It is thickest on the grinding surface of the crown until worn away by attrition, and becomes thinner toward the neck. It consists of a congeries of minute hexagonal rods, columns, or prisms. They lie parallel with one another, resting by one extremity upon the dentine, which presents a number of minute depressions for their reception, and forming the free surface of the crown by the other extremity. These fibres are directed vertically on the summit of the crown, horizontally at the sides; they are about the *3/50* of an inch in diameter, and pursue a more or less wavy course. Each enamel rod is crossed by a series of dark transverse lines, which mark the mode of the formation of the rods (Fig. 563). Another series of lines, having a brown appearance, and denominated the *parallel striæ of Retzius*, or the *colored lines*, are seen on a section of the enamel. These lines are concentric and *cross* the enamel rods. They are caused by the mode of enamel deposition. Inasmuch as the enamel columns, when near the dentine, cross each other and only become parallel farther away, a series of radial markings, light and dark alternately, is obtained (Fig. 561).

Numerous minute interstices intervene between the enamel-fibres near their dentinal surface. It is noted in rare cases that the dentinal fibres penetrate a certain distance between the rods of the enamel. No nutritive canals exist in the enamel.

**Chemical Composition.**—According to Bibra, enamel consists of 96.5 per cent. of earthy matter and 3.5 per cent. of animal matter. The earthy matter consists
of the phosphate with the carbonate of calcium, with traces of fluoride of calcium, phosphate of magnesia, and other salts.

The cortical substance, or cementum (crusta petrosa), is disposed as a thin layer on the roots of the teeth, from the termination of the enamel as far as the apex of the root, where it is usually very thick. In structure and chemical composition it resembles bone. It contains, sparingly, the lacunae and canaliculi which characterize true bone; the lacunae placed near the surface have the canaliculi radiating from the side of the lacunæ toward the periodontal membrane, dental periosteaum, and those more deeply placed join with adjacent dentinal tubuli. In the thicker portions of the crusta petrosa the lamellæ and Haversian canals peculiar to bone are also occasionally found.

As age advances the cement increases in thickness, and gives rise to those bony growths, or exostoses, so common in the teeth of the aged: the pulp-cavity becomes also partially filled up by a hard substance intermediate in structure between dentine and bone (osteo-dentine, Owen; secondary dentine, Tomes). It is formed by the odontoblasts, the dental pulp lessening in volume.

Development of the Teeth.

The teeth are an evolution from the dermoid system, and not of the bony skeleton: they are developed from two of the blastodermic layers, the epiblast and mesoblast. From the former the enamel is developed, from the latter the dental pulp, dentine, cementum, and pericementum. It is customary to view the development of the permanent and temporary teeth as separate studies.

The earliest evidence of tooth-formation in the human embryo is observed in about the seventh week. The mucous membrane covering the embryonic jaws is seen to rise as a longitudinal ridge along the summit of each jaw. A transverse section through the jaws will show the elevation to be due to a linear and outlined activity of the germinal epithelial layer: a corresponding epithelial growth is seen to sink as a band into the mesoblastic tissue beneath. The local cell-activity continues, and in its descent the band appears to meet with a resistance which causes a flattening of its extremity into a continuous lamina. From the inner (toward the tongue) edge of the lamina epithelial cords are given off, ten in number, one for each temporary tooth.

The growth of each cord continues, and each expands into a flask-like form, the walls covered by a layer of germinal cells, its interior by swollen mature cells. The ingrowing bulb is now seen to flatten upon its lower surface, as though it had met with an outlined resistance from the mesoblastic tissue beneath. The epithelial ingrowth assumes the general form of the several teeth; it is the enamel-organ of the tooth (Fig. 564). At this period the mesoblastic tissue around each enamel-organ is seen to become differentiated into fibrous tissue surrounding the enamel-organs, but at some distance from them. Islets of bone are also seen to be forming the beginning of the bony maxilla.

The indentation of the base of the enamel-organ continues until it assumes the form of the future teeth. The cells bounding the organ assume a cylindrical form; the cells of the interior become much expanded, irregular in size and form.

The mesoblastic tissue underlying the enamel-organ is much condensed; evidences of cellular differentiation and a vascular system appear. Bone continues to develop until all of the tooth-follicles are embraced in a gutter of bone. From the lingual side of the cords of the temporary teeth epithelial buds are given off, which sink into the mesoblastic tissue and form the enamel-organs of the permanent teeth. The condensation of fibrous tissue continues until each embryonic tooth is enveloped in a sac, the dental sac; this, together with all of its contents, is called the dental follicle.

The cells of the enamel-organ now undergo a series of differentiations: the inner layer is arranged as columnar epithelium, and is called the ameloblastic or

1 The maxillary rampart of Kolliker Waldeyer.
enamel-forming layer (Figs. 565 and 566). The cells of the outer wall remain cuboidal; the cells which lie between become much distended, and on account of their appearance when seen in section this portion of the organ is called the stellate reticulum (the enamel-jelly). The layer of cells immediately contiguous to the ameloblasts form a layer called the stratum intermedium (Fig. 566A—D).

The enclosed mesoblastic papilla (the future dental pulp) has its peripheral cells differentiated into columnar bodies disposed as a layer, each cell having a large nucleus. The vascular supply of the pulp is now well marked. A section of a follicle at this period will exhibit the follicular wall springing from the base of the dental papilla and having a well-marked blood-supply. The bony alveolar walls are well outlined, and evidences of a periosteum appear (Figs. 565 and 566).

Development of Enamel.—In point of time, the deposition of dentine actually begins before that of enamel, so that the first-formed layer of enamel is deposited against a layer of immature dentine. The enamel is built up of two distinct substances—globules of uniform size which are formed by the ameloblasts, and a cementing substance, probably an albuminate of calcium (calco-globulin), the basis of all the calcified tissues. At the ends of the ameloblasts, next to the dentine, the secretion calco-globulin is deposited, and into the plastic mass the enamel-globules are extruded, each globule remaining connected with the ameloblasts by plasmic strings, which also join the globules laterally.¹

The first deposit of enamel begins in the tips of the cusps, and is quickly followed by a disappearance of the stellate reticulum at that point; the stellate reticulum now appears to atrophy, so that the vascular follicular wall is brought into direct apposition with the stratum intermedium, which becomes differentiated into a glandular (secreting) tissue which elaborates the calcic albuminous basis of the enamel. The secretion passes from the cells of the stratum intermedium through a membrane into the ameloblasts, where it is in part combined with the cellular

¹ J. L. Williams, Dental Cosmos, 1896.
globules, and irregular masses of it extruded as cementing substance. The deposition continues until the enamel-cap has its typical form. The deposition of the layers of globules is indicated by parallel lines transverse to the axes of the enamel-rods. At the completion of amelification the ameloblasts are partially calcified and form the cuticula dentis or Nasmyth’s membrane.

**Formation of Dentine.**—The layer of columnar cells bounding the periphery of the pulp (the odontoblasts) are in apposition with a plexus of capillary vessels (Fig. 566, A). Each cell is a secreting body which selects the material for dentine-building. Against the layer of ameloblasts covering the dental papilla the odontoblasts deposit globules of the calcium albuminate, and, receding as the deposits are made, leave one or more protoplasmic processes in the calcic deposit (Tomes’s fibres). The process continues until the normal dentine thickness is formed. The deposit is laid down in a scaffolding of finely fibrillated tissue. The layer of formative cells remains constant.

**Formation of Cementum.**—Hertwig asserts that the epithelial edge of the enamel-organ formed by the inner and outer epithelial layers of the organ grows downward, or rather the developing tooth grows upward until the future root-form of the tooth is outlined by a double layer of epithelial cells (the root-sheath of Hertwig). The growth of alveolar processes is synchronous.

Upon the pulp side of the sheath a layer of odontoblasts is developed; upon the outer side the fibrous encasement becomes closely attached to the sheath and a layer of osteogenetic cells (cementoblasts) is differentiated. The growth of the dentine of the root is the same as in the crown. The epithelial sheath undergoes atrophic changes, leaving epithelial whorls which remain in the pericementum. The cementum is developed as subperiosteal bone. The cementum over the apex of the root is not formed until after the eruption of the tooth.

**Formation of Alveoli.**—By the time the crowns of the teeth have formed, each
is enclosed in a loculus of bone which has developed around it and at some distance from it; the loculus is open at the top toward the gums, where it is closed by fibrous tissue; the developing permanent tooth is contained in the same loculus, but is later separated from the temporary tooth by a growth of bone. The alveolar process is not completed until after the eruption of the teeth. During eruption that portion of the process overlying the crown undergoes absorption, and as soon as the immature tooth has erupted the alveolar process is developed about the root, whose formation is also completed after eruption.

**Development of the Permanent Teeth.**—The permanent teeth as regards their development may be divided into two sets: (1) those which replace the temporary teeth, and which, like them, are ten in number: these are the *successional permanent teeth*; and (2) those which have no temporary predecessors, but are superadded at the back of the dental series. These are three in number on either side in each jaw, and are termed the *superadded permanent teeth*. They are the three molars of the permanent set, the molars of the temporary set being replaced by the premolars or bicuspids of the permanent set.

The development of the *successional permanent teeth*—the ten anterior ones in either jaw—will be first considered. As already stated, the germ of each milk tooth is a special thickening of the "free" edge of the common dental germ or dental lamina. In like manner is formed the special dental germ of each of the successional permanent teeth. But these thickenings are not at the "free" edge of the dental lamina, but occur behind and lateral to each of the milk-tooth germs (Fig. 564). There are ten of these, and they appear in order, about the sixteenth week, on each side, the central incisor germs being the first.

These special dental germs now go through the same transformations (and become enamel-organs) as were described in connection with those of the milk teeth; that is, they recede into the substance of the gum behind the germs of the temporary teeth. As they recede they become flask-shaped, form an expansion of their distal extremity, and finally meet a papilla, which has been formed in the mesoblast, just in the same manner as was the case in the temporary teeth. The apex of the papilla indentates the dental germ, which enclousits, and forming a cap for it, undergoes analogous changes to those described in the development of the milk teeth, and becomes converted into the enamel, whilst the papilla forms the dentine, of the permanent tooth. In its development it becomes enclosed in a dentinal sac which adheres to the back of the sac of the temporary tooth. The sac of each permanent tooth is also connected with the fibrous tissue of the gum by a slender band or *gubernaculum*, which passes to the margin of the jaw behind the corresponding milk tooth (see above).

The *superadded permanent teeth*—three on each side in each jaw—arise from successive extensions backward—i. e. along the line of the jaw—of the common dental germ from the back part of the special dental germ of the immediately preceding tooth. During the fourth month or seventeenth week, in that portion of the common dental germ which lies behind—i. e. lateral to the special dental germ of the last temporary molar tooth, and which has hitherto remained unaltered, there is developed the special dental germ of the first permanent molar into which a papilla projects. In a similar manner, about the fourth month after birth the second molar is formed, and about the third year the third molar.

**Eruption.**—When the calcification of the different tissues of the milk tooth is sufficiently advanced to enable it to bear the pressure to which it will be afterward subjected, its eruption takes place, the tooth making its way through the gum. The gum is absorbed by the pressure of the crown of the tooth against it, which is itself pressed up by the increasing size of the fang. At the same time the septa between the dentinal sacs, at first fibrous in structure, ossify and thus form the loculi or alveoli; these firmly embrace the necks of the teeth and afford them a solid basis.
THE DEVELOPMENT OF THE TEETH.

Previous to the permanent teeth penetrating the gum, the bony partitions which separate their sacs from the deciduous teeth are absorbed, the roots of the temporary teeth disappear by absorption through the agency of particular multinucleated cells, called odontoclasts, which are developed at the time in the neighborhood of the root, and the permanent teeth become placed under the loose crown of the deciduous teeth; the latter finally become detached, and the permanent teeth take their place in the mouth (Fig. 568).

Calcification of the permanent teeth proceeds in the following order: First molar, soon after birth; the central incisor, lateral incisor, and cuspid, about six months after birth; the bicuspids, at the second year or later; second molar, end of second year; third molar, about the twelfth year.

The eruption of the temporary teeth commences at the seventh month, and is complete about the end of the second year.

The periods for the eruption of the temporary set are (C. S. Tomes)—

The eruption of the permanent teeth takes place at the following periods, the teeth of the lower jaw preceding those of the upper by a short interval:

- 6½ years, first molars.
- 7th year, two middle incisors.
- 8th year, two lateral incisors.
- 9th year, first bicuspid.
- 10th year, second bicuspid.
- 11th to 12th year, canine.
- 12th to 13th year, second molars.
- 17th to 21st year, third molars.
THE PALATE.

The palate forms the roof of the mouth: it consists of two portions, the hard palate in front, the soft palate behind.

The hard palate is bounded in front and at the sides by the alveolar arches and gums; behind, it is continuous with the soft palate. It is covered by a dense structure formed by the periosteum and mucous membrane of the mouth, which are intimately adherent together. Along the middle line is a linear ridge or raphe, which terminates anteriorly in a small papilla (incisive pad) corresponding with the inferior opening of the anterior palatine fossa. This papilla receives filaments from the naso-palatine and anterior palatine nerves. On either side and in front of the raphe the mucous membrane is thick, pale in color, and corrugated; behind, it is thin, smooth, and of a deeper color: it is covered with squamous epithelium, and furnished with numerous glands (palatine glands), which lie between the mucous membrane and the surface of the bone.

The soft palate (velum. pendulun palati) is a movable fold suspended from the posterior border of the hard palate, and forming an incomplete septum between the mouth and pharynx. It consists of a fold of mucous membrane enclosing muscular fibres, an aponeurosis, vessels, nerves, adenoid tissue, and mucous glands. When occupying its usual position (i. e. relaxed and pendent) its anterior surface is concave, continuous with the roof of the mouth, and marked by a median ridge or raphe, which indicates its original separation into two lateral halves. Its posterior surface is convex, and continuous with the mucous membrane covering the floor of the posterior nares. Its upper border is attached to the posterior margin of the hard palate, and its sides are blended with the pharynx. Its lower border is free.

Hanging from the middle of its lower border is a small, conical-shaped pendulous process, the uvula, and arching outward and downward from the base of the uvula on each side are two curved folds of mucous membrane, containing muscular fibres, called the arches or pillars of the soft palate.

The anterior pillars run downward, outward, and forward to the sides of the base of the tongue, and are formed by the projection of the Palato-glossi muscles, covered by mucous membrane.

The posterior pillars are nearer to each other and larger than the anterior; they run downward, outward, and backward to the sides of the pharynx, and are formed by the projection of the Palato-pharyngei muscles, covered by mucous membrane. The anterior and posterior pillars are separated below by a triangular interval in which the tonsil is lodged.

The space left between the arches of the palate on the two sides is called the isthmus of the fauces. It is bounded, above, by the free margin of the soft palate; below, by the back of the tongue; and on each side, by the pillars of the soft palate and the tonsil.

The mucous membrane of the soft palate is thin, and covered with squamous epithelium on its under surface, while on its superior surface the epithelium is columnar and ciliated.1 Beneath the mucous membrane on the oral surface of the soft palate is a considerable amount of adenoid tissue. The palatine glands form a continuous layer on its posterior surface and round the uvula.

The aponeurosis of the soft palate is a thin but firm fibrous layer attached above to the posterior border of the hard palate, and becoming thinner toward the free margin of the velum. Laterally, it is continuous with the pharyngeal aponeurosis. It forms the framework of the soft palate, and is joined by the tendon of the Tensor palati muscle.

The muscles of the soft palate are five on each side: the Levator palati, Tensor palati, Azygos uvule, Palato-glossus, and Palato-pharyngeus (see page 421). The following is the relative position of these structures in a dissection of the soft palate.

1 According to Klein, the mucous membrane on the nasal surface of the soft palate is in the fetus covered throughout by columnar ciliated epithelium, which subsequently becomes squamous.
palate from the posterior or nasal to the anterior or oral surface: Immediately beneath the nasal mucous membrane is a thin stratum of muscular fibres, the posterior fasciculus of the Palato-pharyngeus muscle, joining with its fellow of the opposite side in the middle line. Beneath this is the Azygos uvulae, consisting of two rounded fleshy fasciculi, placed side by side in the median line of the soft palate. Next come the fibres of the Levator palati, joining with the muscle of the opposite side in the middle line. Fourthly, the anterior fasciculus of the Palato-pharyngeus, thicker than the posterior, and separating the Levator palati from the next muscle, the Tensor palati. This muscle terminates in a tendon which, after winding round the hamular process, expands into a broad aponeurosis in the soft palate, anterior to the other muscles which have been enumerated. Finally, we have a thin muscular stratum, the Palato-glossus muscle, placed in front of the aponeurosis of the Tensor palati, and separated from the oral mucous membrane by adenoid tissue.

The tonsils (amygdalae) are two glandular organs, situated one on each side of the fauces, between the anterior and posterior pillars of the soft palate. They are of a rounded form, and vary considerably in size in different individuals. Externally the tonsil is in relation with the inner surface of the Superior constrictor, which separates it from the internal carotid and ascending pharyngeal arteries. It corresponds to the angle of the lower jaw. Its inner surface presents from twelve to fifteen orifices, leading into small recesses, from which numerous follicles branch out into the substance of the gland. These follicles are lined by a continuation of the mucous membrane of the pharynx, covered with epithelium; around each follicle is a layer of closed capsules imbedded in the submucous tissue. These capsules are analogous to those of Peyer's glands, consisting of adenoid tissue. No openings from the capsules into the follicles can be recognized. They contain a thick grayish secretion. Surrounding each follicle is a close plexus of lymphatic vessels. From these plexuses the lymphatic vessels pass to the deep cervical glands in the upper part of the neck, which frequently become enlarged in affections of these organs.

The arteries supplying the tonsil are the dorsalis linguae from the lingual, the ascending palatine and tonsillar from the facial, the ascending pharyngeal from the external carotid, the descending palatine branch of the internal maxillary, and a twig from the small meningeal.

The veins terminate in the tonsillar plexus, on the outer side of the tonsil.

The nerves are derived from Meckel's ganglion and from the glosso-pharyngeal.

The salivary glands (Fig. 569).

The principal salivary glands communicating with the mouth and pouring their secretion into its cavity are the parotid, submaxillary, and sublingual.

The parotid gland, so called from being placed near the ear (παροτ, near; ωτ, ωτῶς, the ear), is the largest of the three salivary glands, varying in weight from half an ounce to an ounce. It lies upon the side of the face immediately below and in front of the external ear. It is limited above by the zygoma; below, by the angle of the jaw and by a line drawn between it and the mastoid process: anteriorly, it extends to a variable extent over the Masseter muscle; posteriorly, it is bounded by the external meatus, the mastoid process, and the Sterno-mastoid and Digastric muscles, slightly overlapping the latter.

Its anterior surface is grooved to embrace the posterior margin of the ramus of the lower jaw, and advances forward beneath the ramus, between the two Pterygoid muscles and in front of the ramus over the Masseter muscle. Its outer surface, slightly lobulated, is covered by the integument and parotid fascia, and has one or two lymphatic glands resting on it. Its inner surface extends deeply into the neck by means of two large processes, one of which dips behind the styloid process and projects beneath the mastoid process and the Sterno-mastoid muscle; the other is
situated in front of the styloid process, and passes into the back part of the glenoid fossa, behind the articulation of the lower jaw. The structures passing through the parotid gland are—the external carotid artery, giving off its three terminal branches: the posterior auricular artery emerges from the gland behind; the temporal artery above; the transverse facial, a branch of the temporal, in front; and the internal maxillary winds through it as it passes inward, behind the neck of the jaw. Superficial to the external carotid is the trunk formed by the union of the temporal and internal maxillary veins; a branch, connecting this trunk with the internal jugular, also passes through the gland. It is also traversed by the facial nerve and its branches, which emerge at its anterior border; branches of the great auricular nerve pierce the gland to join the facial, and the auriculo-temporal branch of the inferior maxillary nerve emerges from the upper part of the gland. The internal carotid artery and internal jugular vein lie close to its deep surface.

The duct of the parotid gland (Stenson's) is about two inches and a half in length. It commences by numerous branches from the anterior part of the gland, crosses the Masseter muscle, and at its anterior border dips down into the substance of the Buccinator muscle, which it pierces; it then runs for a short distance obliquely forward between the Buccinator and mucous membrane of the mouth, and opens upon the inner surface of the cheek by a small orifice opposite the second molar tooth of the upper jaw. While crossing the Masseter it receives the duct of a small detached portion of the gland, socia parotidis, which occasionally exists as a separate lobe, just beneath the zygomatic arch. In this position it has the transverse facial artery above it and some branches of the facial nerve below it.

Structure.—The parotid duct is dense, of considerable thickness, and its canal about the size of a crowquill; it consists of an external or fibrous coat, of considerable density, containing contractile fibres, and of an internal or mucous coat lined with short columnar epithelium.
Surface Form.—The direction of the duct corresponds to a line drawn across the face about a finger’s breadth below the zygoma; that is, from the lower part of the tragus to midway between the free margin of the upper lip and the ala of the nose.

Vessels and Nerves.—The arteries supplying the parotid gland are derived from the external carotid, and from the branches given off by that vessel in or near its substance. The veins empty themselves into the external jugular through some of its tributaries. The lymphatics terminate in the superficial and deep cervical

![Diagram](https://via.placeholder.com/150)

Fig. 570.—A highly magnified section of the submaxillary gland of the dog, stained with carmine. (Körllken.)

glands, passing in their course through two or three lymphatic glands placed on the surface and in the substance of the parotid. The nerves are derived from the carotid plexus of the sympathetic, the facial, the auriculo-temporal, and great auricular nerves.

It is probable that the branch from the auriculo-temporal nerve is derived from the glosso-pharyngeal through the otic ganglion (which see). At all events, in some of the lower animals this has been proved experimentally to be the case.

The submaxillary gland is situated below the jaw, in the anterior part of the submaxillary triangle of the neck. It is irregular in form and weighs about two drachms (8-10 grammes). It is covered by the integument, Platysma, deep cervical fascia, and the body of the lower jaw, corresponding to a depression on the inner surface of the bone, and lies upon the Mylo-hyoid, Hyo-glossus, and Styloglossus muscles, a portion of the gland passing beneath the posterior border of the Mylo-hyoid. In front of it is the anterior belly of the Digastric; behind, it is separated from the parotid gland by the stylo-maxillary ligament, and from the sublingual gland in front by the Mylo-hyoid muscle. The facial artery lies imbedded in a groove in its posterior and upper border.

The duct of the submaxillary gland (Wharton’s) is about two inches in length, and its walls are much thinner than those of the parotid duct. It commences by numerous branches from the deep portion of the gland, and passes forward and inward between the Mylo-hyoid and the Hyo-glossus and Genio-hyoid muscles, then between the sublingual gland and the Genio-hyoid-glossus, and opens by a narrow orifice on the summit of a small papilla at the side of the frenum linguae. On the Hyo-glossus muscle it lies between the lingual and hypoglossal nerves, but at the anterior border of the muscle it crosses under the lingual nerve, and is then placed above it.

Vessels and Nerves.—The arteries supplying the submaxillary gland are branches of the facial and lingual. Its veins follow the course of the arteries. The nerves are derived from the submaxillary ganglion, through which it receives filaments from the chorda tympani of the facial and lingual branch of the inferior maxillary, from the mylo-hyoid branch of the inferior dental, and from the sympathetic.
The sublingual gland is the smallest of the salivary glands. It is situated beneath the mucous membrane of the floor of the mouth, at the side of the frenum linguae, in contact with the inner surface of the lower jaw, close to the symphysis. It is narrow, flattened, in shape somewhat like an almond, and weighs about a drachm. It is in relation, above, with the mucous membrane; below, with the Mylo-hyoid muscle; in front, with the depression on the side of the symphysis of the lower jaw, and with its fellow of the opposite side; behind, with the deep part of the submaxillary gland; and internally, with the Genio-hyo-glossus, from which it is separated by the lingual nerve and Wharton's duct. Its excretory ducts (ducts of Rivinus), from eight to twenty in number, open separately into the mouth; on the elevated crest of mucous membrane caused by the projection of the gland, on either side of the frenum linguae. One or more join to form a tube which opens into the Whartonian duct; this is called the duct of Bartholin.

Vessels and Nerves.—The sublingual gland is supplied with blood from the sublingual and submental arteries. Its nerves are derived from the lingual.

Structure of Salivary Glands.—The salivary are compound racemose glands, consisting of numerous lobes, which are made up of smaller lobules connected together by dense areolar tissue, vessels, and ducts. Each lobule consists of the ramifications of a single duct, "branching frequently in a tree-like manner," the branches terminating in dilated ends or alveoli, on which the capillaries are distributed. These alveoli, however, as Pflüger points out, are not necessarily spherical, though sometimes they assume that form; sometimes they are perfectly cylindrical, and very often they are mutually compressed. The alveoli are enclosed by a basement membrane which is continuous with the membrana propria of the duct. It presents a peculiar reticulated structure, having the appearance of a basket with open meshes, and consisting of a network of branched and flattened nucleated cells.

The alveoli of the salivary glands are of two kinds, which differ both in the appearance of their secreting cells, in their size, and in the nature of their secretion. The one variety secretes a ropy fluid which contains mucin, and has therefore been named the mucus, whilst the other secretes a thinner and more watery fluid, which contains serum-albumin, and has been named serous or albuminous. The sublingual gland may be regarded as an example of the former variety, the parotid of the latter. The submaxillary is of the mixed variety, containing both mucous and serous alveoli, the latter, however, preponderating.

Both alveoli are lined by cells, and it is by the character of these cells that the nature of the gland is chiefly to be determined. In addition, however, the alveoli of the serous glands are smaller than those of the mucous ones.

The cells in the mucous alveoli are spheroidal in shape, glassy, transparent, and dimly striated in appearance. The nucleus is usually situated in the part of the cell which is next the basement membrane, against which it is sometimes flattened. The most remarkable peculiarity presented by these cells is, that they give off an extremely fine process, which is curved in a direction parallel to the surface of the alveolus, lies in contact with the membrana propria, and overlaps the process of neighboring cells. The cells contain a quantity of mucin, to which their clear, transparent appearance is due.

Here and there in the alveoli are seen peculiar half-moon-shaped bodies lying between the cells and the membrana propria of the alveolus. They are termed the crescents of Gianuzzi or the demilunes of Heidenhain (Fig. 570), and are regarded by Pflüger as due to post-mortem change, but by most other later observers they are believed to be composed of polyhedral granular cells, which Heidenhain regards as young epithelial cells destined to supply the place of those salivary cells which have undergone disintegration. This view, however, is not accepted by Klein.

Serous Alveoli.—In the serous alveoli the cells almost completely fill the cavity,
so that there is hardly any lumen perceptible. Instead of presenting the clear, transparent appearance of the cells of the mucous alveoli, they present a granular appearance, due to distinct granules of an albuminous nature imbedded in a closely-reticulated protoplasm. The ducts which originate out of the alveoli are lined at their commencement by epithelium which differs little from the pavement type. As the ducts enlarge the epithelial cells change to the columnar type, and they are described by Pflüger as attached to the basement membrane by a brush of fine hair-like processes, which he believes to be continuous with the nerve-fibres. Other anatomists regard these cells as merely striated on their deep surface. The lobules of the salivary glands are richly supplied with blood-vessels which form a dense network in the interalveolar spaces. Fine plexuses of nerves are also found in the interlobular tissue.

Pflüger describes the nerves as being directly continuous with the salivary cells of the alveolus, the nerve some-

![Diagram](image)

Fig. 571.—Illustrating Pflüger's views of the termination of the nerves in the alveolar cells. (From Stricker's 'Handbook.') A. Direct passage of nerve into a salivary cell. B. By the medium of a multipolar ganglion-cell, g.

times passing through a ganglion-cell just before joining the alveolus (Fig. 571, A and B). This fact has not, however, been corroborated by other observers. There is no doubt that ganglia are to be found in some salivary glands in connection with the nerve-plexuses in the interlobular tissue; thus they are to be found in the submaxillary, but not in the parotid, but whether the ultimate fibrils are connected with the salivary cells, as asserted by Pflüger, remains to be proved.

In the submaxillary and sublingual glands the lobes are larger and more loosely united than in the parotid.

Mucous Glands.—Besides the salivary glands proper, numerous other glands are found in the mouth. They appear to secrete mucus only, which serves to keep the mouth moist during the intervals of the salivary secretion, and which is mixed with that secretion in swallowing. Many of these glands are found at the posterior part of the dorsum of the tongue, behind the circumvallate papilla, and also along its margins as far forward as the apex. Others lie around and in the tonsil between its crypts, and a large number in the soft palate. These glands are of the ordinary compound racemose type.

Surface Form.—The orifice of the mouth is bounded by the lips, two thick, fleshy folds covered externally by integument and internally by mucous membrane, and consisting of muscles, vessels, nerves, areolar tissue, and numerous small glands. The size of the orifice of the mouth varies considerably in different individuals, but seems to bear a close relation to the size and prominence of the teeth. Its corners correspond pretty accurately to the outer border of the canine teeth. In the Mongolian tribes, where the front teeth are large and inclined forward, the mouth is large; and this, combined with the thick and everted lips which appear to be associated with prominent teeth, gives to the negro's face much of the peculiarity by which it is characterized. The smaller teeth and the slighter prominence of the alveolar arch of the

1 It has recently been shown by Ehner that many of these glands open into the trenches around the circumvallate papilla, and that their secretion is more watery than that of ordinary mucous glands. He supposes that they assist in the more rapid distribution of the substance to be tasted over the region where the special apparatus of the sense of taste is situated.
more highly civilized races render the orifice of the mouth much smaller, and thus a small mouth is an indication of intelligence, and is regarded as an evidence of the higher civilization of the individual.

Upon looking into the mouth, the first thing we may note is the tongue, the upper surface of which will be seen occupying the floor of the cavity. This surface is convex, and is marked along the middle line by a raphe which divides it into two symmetrical portions. The anterior two-thirds is rough and studded with papillae; the posterior third smooth and tuberculated, covered by numerous glands which project from the surface. Upon raising the tongue the mucous membrane which invests the upper surface may be traced covering the sides of the under surface, and then reflected over the floor of the mouth on to the inner surface of the lower jaw, a part of which it covers. As it passes over the borders of the tongue it changes its character, becoming thin and smooth and losing the papillae which are to be seen on the upper surface. In the middle line the mucous membrane on the under surface of the tip of the tongue forms a distinct fold, the frenum lingue, by which this organ is connected to the symphysis of the jaw. Occasionally it is found that this frenum is rather shorter than natural, and, acting as a bridle, prevents the complete protrusion of the tongue. When this condition exists and an attempt is made to protrude the organ, the tip will be seen to remain buried in the floor of the mouth, and the dorsum of the tongue is rendered very convex, and more or less extruded from the mouth; at the same time a deep furrow will be noticed in the middle line of the anterior part of the dorsum. Sometimes, a little external to the frenum, the canine vein may be seen immediately beneath the mucous membrane. The corresponding artery, being more deeply placed, does not come into view, nor can its pulsation be felt with the finger. On either side of the frenum, in the floor of the mouth, is a longitudinal elevation or ridge, produced by the projection of the sublingual gland, which lies immediately beneath the mucous membrane. And close to the attachment of the frenum to the tip of the tongue may be seen on either side the slit-like orifices of Wharton's ducts, into which a fine probe may be passed without much difficulty. By exerting the lips the smooth mucous membrane lining them may be examined, and may be traced from the mucous membrane of the lips to the faucial or post-McNeal's membrane. In the middle line, both of the upper and lower lip, a small fold of mucous membrane passes from the lip to the bone, constituting the frenum; these are not so large as the frenum lingue. By pulling outward the angle of the mouth, the mucous membrane lining the cheeks can be seen, and on it may be perceived a little papilla which marks the position of the orifice of Stenson's duct—the duct of the parotid gland. The exact position of the orifice of the duct will be found to be opposite the second molar tooth of the upper jaw. The introduction of a probe into this duct is attended with considerable difficulty. The teeth are the next objects which claim our attention upon looking into the mouth. There are, as stated above, ten in either jaw in the temporary set, and sixteen in the permanent set. The gums, in which they are implanted, are dense, firm, and vascular.

At the back of the mouth is seen the isthmus of the fauces, or, as it is popularly called, "the throat": this is the space between the pillars of the fauces on either side, and is the means by which the mouth communicates with the pharynx. Above, it is bounded by the soft palate, the anterior surface of which is concave and covered with mucous membrane, which is continuous with that lining the roof of the mouth. Projecting from the middle of its lower border is a conical-shaped projection, the uvula. On either side of the isthmus of the fauces are the anterior and posterior pillars, formed by the Palato-glossus and Palato-pharyngeus muscles respectively, covered over by mucous membrane. Between the two pillars on either side is situated the tonsil. By their external surface these glands are in close relationship with the internal carotid artery, being separated from this vessel only by the thin plane of muscular fibres forming the wall of the pharynx. It is stated that this vessel may be wounded in remov- ing the tonsil. The extirpation of this glandular body is not unattended with danger of hemorrhage from other sources. Dr. Weir has stated that he believes that when hemorrhage occurs after their removal it arises from one of the palatine arteries having been wounded. These vessels are large: they lie in the muscular tissue of the palate, and when wounded are constantly exposed to disturbance from the contraction of the palatine muscles. The vessels of the tonsil, Dr. Weir states, are small and lie in the soft tissue, and readily contract when wounded.

When the mouth is wide open a prominent tense fold of mucous membrane may be seen and felt, extending upward and backward from the position of the fung of the last molar tooth to the posterior part of the hard palate. This is caused by the Pterygo-maxillary ligament, which is attached by one extremity to the apex of the internal pterygoid plate, and by the other to the posterior extremity of the mylo-hyoid ridge of the lower jaw. It connects the Buccinator with the Superior constrictor of the pharynx. The fung of the last molar tooth indicates the position of the lingual (gustatory) nerve, where it is easily accessible, and can with readiness be divided in cases of cancer of the tongue (see page 810). On the inner side of the last molar tooth we can feel the humoral process of the internal pterygoid plate of the sphenoid bone, around which the tendon of the Tensor palati plays. The exact position of this process is of importance in performing the operation of staphylorraphy. About one-third of an inch in front of the hamular process, and the same distance directly inward from the last molar tooth, is the situation of the opening of the posterior palatine canal, through which emerges the posterior or descending palatine branch of the internal maxillary artery and one of the descending palatine nerves from Meckel's ganglion. The exact position of the opening on the subject may
be ascertained by driving a needle through the tissues of the palate in this situation, when it
will be at once felt to enter the canal. The artery emerging from the opening runs forward in a
groove in the bone just internal to the alveolar border of the hard palate, and may be wounded
in the operation for the cure of cleft palate. Under these circumstances the palatine canal may
require plugging. By introducing the finger into the mouth the anterior border of the coronoid
process of the jaw can be felt, and is especially prominent when the jaw is dislocated. By
throwing the head well back a considerable portion of the posterior wall of the pharynx may be
seen through the isthmus faucium, and on introducing the finger the anterior surface of the
bodies of the upper cervical vertebrae may be felt immediately beneath the thin muscular stra-
tum forming the wall of the pharynx. The finger can be hooked around the posterior border of
the soft palate, and by turning it forward the posterior nares, separated by the septum, can
be felt, or the presence of any adenoid or other growths in the naso-pharynx ascertained.

THE PHARYNX.

The pharynx is that part of the alimentary canal which is placed behind the
nose, mouth, and larynx. It is a musculo-membranous sac, somewhat conical in
form, with the base upward and the apex downward, extending from the under
surface of the skull to the cricoid cartilage in front and the intervertebral disk
between the fifth and sixth cervical vertebrae behind.

The pharynx is about four inches and a half in length, and broader in the
transverse than in the antero-posterior diameter. Its greatest breadth is opposite
the cornua of the hyoid bone; its narrowest point, at its termination in the
œsophagus. It is limited, above, by the body of the sphenoid and basilar process
of the occipital bone; below, it is continuous with the œsophagus; posteriorly, it
is connected by loose areolar tissue with the cervical portion of the vertebral
column and the Longi colli and Recti capitis antici muscles; anteriorly, it is
incomplete, and is attached in succession to the internal pterygoid plate, the
pterygo-maxillary ligament, the lower jaw, the tongue, hyoid bone, and thyroid and
cricoid cartilages; laterally, it is connected to the styloid processes and their mus-
cles, and is in contact with the common and internal carotid arteries, the internal
jugular veins, and the glosso-pharyngeal, pneumogastric, hypoglossal, and symp-
pathetic nerves, and above with a small part of the Internal pterygoid muscles.

It has seven openings communicating with it—the two posterior nares, the
two Eustachian tubes, the mouth, larynx, and œsophagus.

The posterior nares are the two oval openings (see page 222) situated at the
upper part of the anterior wall of the pharynx.

The two Eustachian tubes open one at each side of the upper part of the
pharynx, at the back part of the inferior meatus. Below the posterior nares are
the posterior surface of the soft palate and uvula, the large aperture of the
mouth, the base of the tongue, the epiglottis, and the cordiform opening of the
larynx.

The œsophageal opening is the lower contracted portion of the pharynx.

Structure.—The pharynx is composed of three coats—mucous, fibrous, and
muscular.

The pharyngeal aponeurosis, or fibrous coat, is situated between the mucous
and muscular layers. It is thick above, where the muscular fibres are wanting, and
is firmly connected to the basilar process of the occipital and petrous portion of the
temporal bones. As it descends it diminishes in thickness, and is gradually lost.
It is strengthened posteriorly by a strong fibrous band which is attached above to
the pharyngeal spine on the under surface of the basilar portion of the occipital
bone, and passes downward, forming a median raphe, which gives attachment to the
Constrictor muscles of the pharynx.

The mucous coat is continuous with that lining the Eustachian tubes, the nares,
the mouth, and the larynx. It is covered by columnar ciliated epithelium, as low
down as on a level with the floor of the nares; below that point the epithelium is of
the squamous variety. Beneath the mucous membrane are found racemose mucous
glands; they are especially numerous at the upper part of the pharynx around the
orifices of the Eustachian tubes. Throughout the pharynx are also numerous crypts
or recesses, the walls of which are surrounded by lymphoid tissue similar to what
is found in the tonsils. Across the back part of the pharyngeal cavity, between the two Eustachian tubes, a considerable mass of this tissue exists, and has been named the pharyngeal tonsil. Just below this in the middle line is the orifice of an irregular, flask-shaped recess of the mucous membrane, extending up as far as the basilar process of the occipital bone. It is known as the bursa pharyngea, and is the remains of the diverticulum of the alimentary canal, which is concerned in the development of the pituitary body (which see). It is only occasionally present in the adult.

The muscular coat has been already described (page 419).

Surgical Anatomy.—The internal carotid artery is in close relation with the pharynx, so that its pulsations can be felt through the mouth. It has been occasionally wounded by sharp-pointed instruments introduced into the mouth and thrust through the wall of the pharynx. In aneurism of this vessel in the neck the tumor necessarily bulges into the pharynx, as this is the direction in which it meets with the least resistance, nothing lying between the vessel and the mucous membrane except the thin Constrictor muscle, whereas on the outer side there is the dense cervical fascia, the muscles descending from the styloid process, and the margin of the Sterno-mastoid.

The mucous membrane of the pharynx is very vascular, and is often the seat of inflammation, frequently of a septic character, and dangerous on account of its tendency to spread to the Larynx. On account of the tissue which surrounds the pharyngeal wall being loose and lax, the inflammation is liable to spread through it far and wide, extending downward into the posterior mediastinum along the oesophagus. Abscess may form in the connective tissue behind the pharynx, between it and the vertebral column, constituting what is known as post-pharyngeal abscess. This is most commonly due to caries of the cervical vertebrae, but may also be caused by suppuration of a lymphatic gland which is situated in this position opposite the axis, and which receives lymphatics from the nares, or by a gumma or by acute pharyngitis. The abscess may be most easily evacuated by an incision, with a guarded bistoury, through the mouth. It has recently been proposed to open the abscess aseptically by an incision in the neck behind the Sterno-mastoid. The operation, however, is a difficult one, unless the abscess is pointing laterally, and does not give such free access to the seat of disease for the removal of necrosed bone, if any exists, and does not appear to present sufficient advantages to warrant its performance.

Foreign bodies not unfrequently become lodged in the pharynx, and most usually at its termination at about the level of the cricoid cartilage, just beyond the reach of the finger, as the distance from the arch of the teeth to the commencement of the oesophagus is about six inches.

The position of the openings of the Eustachian tubes should be studied with a view to catheterism of these tubes. This is to be done by introducing the instrument through the anterior nares, so that its points rest on the floor of the nasal cavity close to the septum; it is then pushed gradually and slowly backward until the posterior wall of the pharynx is reached. Then having been slightly withdrawn so as to free the point from the wall of the pharynx, it is rotated outward and upward, so that the ring of the instrument is turned toward the external ear, and it can then be made to glide into the Eustachian tube.

THE OESOPHAGUS.

The oesophagus, or gullet, is a muscular canal, about nine inches (23 centim.) in length, extending from the pharynx to the stomach. When empty its lumen appears as a transverse slit. Its diameter varies from 1.8 to 2.4 centim. It commences at the upper border of the cricoid cartilage, opposite the intervertebral disk between the fifth and sixth cervical vertebrae, descends along the front of the spine through the posterior mediastinum, passes through the Diaphragm, and, entering the abdomen, terminates at the cardiac orifice of the stomach opposite the tenth dorsal vertebra or the intervertebral disk between the tenth and eleventh dorsal vertebrae. The general direction of the oesophagus is vertical, but it presents two or three slight curves in its course. At its commencement it is placed in the median line, but it inclines to the left side as far as the root of the neck, gradually passes to the middle line again, and finally again deviates to the left as it passes forward to the esophageal opening of the Diaphragm. The oesophagus also presents an antero-posterior flexure, corresponding to the curvature of the cervical and thoracic portions of the spine. It is the narrowest part of the alimentary canal, being most contracted at its commencement and at the point where it passes through the Diaphragm.

Relations.—In the neck the oesophagus is in relation, in front, with the trachea, and at the lower part of the neck, where it projects to the left side, with
the thyroid gland and thoracic duct; behind, it rests upon the vertebral column and Longi colli muscles; on each side, it is in relation with the common carotid artery (especially the left, as it inclines to that side) and part of the lateral lobes of the thyroid gland; the recurrent laryngeal nerves ascend between it and the trachea.

In the thorax it is at first situated a little to the left of the median line; it then passes behind the left side of the aortic arch, and descends in the posterior mediastinum, along the right side of the aorta, nearly to the Diaphragm, where it passes in front and a little to the left of the artery, previous to entering the abdomen. It is in relation, in front, with the trachea, the arch of the aorta, left carotid, and left subclavian arteries, the left bronchus, and the posterior surface of the pericardium; behind, it rests upon the vertebral column, the Longi colli muscles, the thoracic duct (opposite middle dorsal vertebræ), the right intercostal vessels, and below, near the Diaphragm, upon the front of the aorta; laterally, it is covered by the pleura: the vena azygos major lies on the right and the descending aorta on the left side. The pneumogastric nerves descend in close contact with it on each side; lower down the right nerve passes behind, and the left nerve in front of it.

Structure.—The oesophagus has three coats—an external or muscular; a middle or areolar; and an internal or mucous coat.

The muscular coat is composed of two planes of fibres of considerable thickness, an external longitudinal and an internal circular.

The longitudinal fibres are arranged, at the commencement of the tube, in three fasciculi: one in front, which is attached to the vertical ridge on the posterior surface of the cricoid cartilage; and one at each side, which is continuous with the fibres of the Inferior constrictor: as they descend they blend together and form a uniform layer, which covers the outer surface of the tube.

Accessory slips of muscular fibres are described by Dr. Cunningham as passing between the oesophagus and the pleura, where it covers the thoracic aorta (almost always), or the root of the left bronchus (usually), or the back of the pericardium or corner of the mediastinum (more rarely), as well as other still more rare accessory fibres. In Fig. 572, taken from a dissection in the Museum of the Royal College of Surgeons, several of these accessory slips may be seen passing from the oesophagus to the pleura, and two slips to the back of the trachea just above its bifurcation.

The circular fibres are continuous above with the Inferior constrictor; their direction is transverse at the upper and lower parts of the tube, but oblique in the central part.

The muscular fibres in the upper part of the oesophagus are of a red color, and consist chiefly of the striped variety, but below they consist for the most part of involuntary muscular fibre.

The areolar coat connects loosely the mucous and muscular coats.

The mucous coat is thick, of a reddish color above and pale below. It is disposed in longitudinal folds, which disappear on distension of the tube. Its surface is studded with minute papille, and it is covered throughout with a thick layer of stratified pavement epithelium. Beneath the mucous membrane, between it and the areolar coat, is a layer of longitudinally arranged non-striped muscular fibres. This is the muscularis mucosae. At the commencement it is absent, or only represented by a few scattered bundles; lower down it forms a considerable stratum.

The oesophageal glands are numerous small compound racemose glands scattered throughout the tube; they are lodged in the submucous tissue, and open upon the surface by a long excretory duct. They are most numerous at the lower part of the tube, where they form a ring round the cardiac orifice.

Vessels of the Oesophagus.—The arteries supplying the oesophagus are derived from the inferior thyroid branch of the thyroid axis of the subclavian, from the descending thoracic aorta, and from the gastric branch of the coeliac
axis from the abdominal aorta. They have for the most part a longitudinal direction.

Nerves of the Oesophagus.—The nerves are derived from the pneumogastric and from the sympathetic; they form a plexus in which are groups of ganglion-cells between the two layers of the muscular coats, and also a second plexus in the submucous tissue.

Surgical Anatomy.—The relations of the oesophagus are of considerable practical interest to the surgeon, as he is frequently required, in cases of stricture of this tube, to dilate the canal by a bougie, when it is of importance that the direction of the oesophagus and its relations to surrounding parts should be remembered. In cases of malignant disease of the oesophagus, where its tissues have become softened from infiltration of the morbid deposit, the greatest care is requisite in directing the bougie through the strictured part, as a false passage may easily be made, and the instrument may pass into the mediastinum, or into one or the other plural cavity, or even into the pericardium.

The student should also remember that contraction of the oesophagus, and consequent symptoms of stricture, are occasionally produced by an aneurism of some part of the aorta pressing upon this tube. In such a case the passage of a bougie could only hasten the fatal issue.

In passing a bougie the left fore finger should be introduced into the mouth and the epiglottis felt for, care being taken not to throw the head too far backward. The bougie is then to be passed beyond the finger until it touches the posterior wall of the pharynx. The patient is now asked to swallow, and at the moment of swallowing the bougie is passed gently onward, all violence being carefully avoided.

It occasionally happens that a foreign body becomes impacted in the oesophagus which can neither be brought upward nor moved downward. When all ordinary means for its removal have failed, excision is the only resource. This, of course, can only be performed when it is not very low down. If the foreign body is allowed to remain, extensive inflammation and ulceration of the oesophagus may ensue. In one case the foreign body ultimately penetrated the intervertebral substance, and destroyed life by inflammation of the membranes and substance of the cord.

The operation of oesophagotomy is thus performed: The patient being placed upon his back, with the head and shoulders slightly elevated, an incision, about four inches in length, should be made on the left side of the trachea, from the thyroid cartilage downward, dividing the skin and Platysma. The edges of the wound being separated, the Omo-hyoid muscle should, if necessary, be divided, and the fibres of the Sterno-hyoid and Sterno-thyroid muscles drawn inward; the sheath of the carotid vessels, being exposed, should be drawn outward, and retained in that position by retractors: the oesophagus will now be exposed, and should be divided over the foreign body, which can then be removed. Great care is necessary to avoid wounding the thyroid vessels, the thyroid gland, and the laryngeal nerves.

The oesophagus may be obstructed not only by foreign bodies, but also by changes in its coats, producing stricture, or by pressure on it from without of new growths or aneurism, etc.

The different forms of stricture are: (1) the spasmodic, usually occurring in nervous women, and intermittent in character, so that the dysphagia is not constant; (2) fibrous, due to cicatrisation after injuries, such as swallowing corrosive fluids or boiling water; and (3) malignant, usually epitheliomatous in its nature. This is situated generally either at the upper end of the tube, opposite to the cricoid cartilage, or at its lower end at the cardiac orifice, but is also occasionally found at that part of the tube where it is crossed by the left bronchus.

The operation of oesophagostomy has occasionally been performed in cases where the stricture in the oesophagus is at the upper part, with a view to making a permanent opening below the stricture through which to feed the patient, but the operation has been far from a successful one, and the risk of setting up diffuse inflammation in the loose planes of connective tissue deep in the neck is so great that it would appear to be better to perform gastrostomy.
THE ABDOMEN.
[By Fred J. Brockway, M. D.,
Asst. Demonstrator of Anatomy, College of Physicians and Surgeons (Columbia University) New York City.]

In the early stages of the embryo the "body-cavity" (pleuro-peritoneal cavity) is of large size. Anteriorly (i.e. superiorly in the erect posture) there is developed a comparatively enormous space, called the pericardio-thoracic cavity (Fig. 573, A, B and C). There also appears a transverse fold marking off this cavity in part from the future abdominal cavity. This fold, associated with many large veins, is next developed into the primary diaphragm, but its dorsal part is incomplete. This is completed later, constituting the diaphragm as we know it in the adult. The diaphragm is thus made up of a ventral younger part and a dorsal older part. When this posterior part fails of development, there is an opportunity for the "congenital diaphragmatic hernia" to be present.

The superior or pericardio-thoracic cavity becomes separated into three distinct compartments (Fig. 573, B and C), the two lateral being continuous for a time with the abdominal cavity. Thus are formed the four large serous spaces of the body, each one lined with serous membrane. Two are thoracic or pleural, lined with pleura, one is cardiac, defined by the pericardial sac, and one is abdominal, lined with peritoneum.

The word abdomen\(^1\) is applied to the part of the body lying between the thorax and pelvis; it refers to the largest cavity of the adult body, and is often applied incorrectly to the anterior wall of this cavity. It contains nearly all the digestive apparatus and a part of the urinary system.

Superficially the abdomen is marked from the thorax above by the costal arches, and below from the pelvis by the crests of the ilia, and from the thighs by Poupart's ligaments. These limits, however, do not correspond with those of the abdominal cavity. This extends high into the thorax to the cupola of the diaphragm. The lowest limit is the so-called "diaphragm of the pelvis" made by the Levator ani and Coccygeus muscles on either side. This great cavity shows a smaller artificial subdivision, the pelvic cavity (Fig. 577). The two are not separated, but the limit between them is taken as the brim of the true pelvis.

---
\(^1\) Abdo\'men comes perhaps from abdēre, to conceal. Hyrtl says it is an ancient word applied to the belly of a pregnant pig. Cicero transferred it from swine to man in a sense of contempt. Venter and aevus were used for belly; abdomen and its adjective abdominalis finally came into general use.
the *linea innominata*. The larger upper cavity is called the *abdominal cavity proper*.

The *form and extent* of the abdomen vary with age and sex. In the *adult male* with intestines moderately distended it is barrel-shaped or oval, somewhat flattened from before backward (Fig. 574, A, B, and C). The *infantile type* is conical with apex below, as the pelvis is undeveloped. In *woman* the type is a reversed infantile, regardless of so-called civilized dress. The circumference of the fully-developed pelvis here is always larger than that of the lower end of the thorax.
Boundaries.—The abdomen proper is divided for description into the abdominal wall or boundaries and the abdominal cavity and contents. The boundaries are a roof, a floor, and the wall, which includes an antero-lateral and a posterior portion; the former is soft and contractile, muscular on the sides, fibrous and aponeurotic in the centre; the posterior wall is partly osseous, ligamentous and muscular.

Several facts depend on the character of the antero-lateral wall. It does not offer to the viscera and great vessels a passive protection as does the skull to its contents, but allows a mutual reaction which is of the greatest importance. It yields lightly to every pressure and corresponds to the changing volume of the intestines and to the changes of position and form of the viscera. Atmospheric pressure acts on every side, but this is overlooked when the many muscles are considered which exert a constant tension. The relations of each organ to its neighbor are modified by this tension, and soft organs like the liver, pancreas, or spleen are moulded by it and show the imprint of nearly every viscus that touches them. The tension is seen in cases of penetrating wounds, where the movable intestines tend to flow toward the spot of least resistance and are replaced or restrained with difficulty. The same pressure helps to develop hernia and forces the portal circulation through the liver.

The shape of the soft antero-lateral wall depends upon the degree of distention of the alimentary canal, the size of the parenchymatous organs, and especially upon the deposit of fat in the subcutaneous tissue, in the peritoneal folds, and in the great omentum. All gradations occur between the great fat belly which depends over the thighs and the concave trough-like one of a thin person. The pliability and thinness of the wall allow palpation to be of more value here in diagnosis than percussion.

The component parts of the walls have already been discussed. A brief review is here added (Fig. 575).

In the antero-lateral wall from without inward are found in order:
1. Skin.
2. Superficial fascia, two layers.
3. Cellular tissue covering the External oblique muscle, and intercolumnar fascia from the external abdominal ring.
4. Muscles of the wall. Broad muscles—the External oblique and aponeurosis, the Internal oblique and aponeurosis, the Transversalis and aponeurosis. Longitudinal muscles—the Rectus and Pyramidalis.
5. Fascia transversalis.
6. Subperitoneal cellular tissue.
7. Peritoneum.

In this wall several regions are described: the inguinal, inguino-femoral, and umbilical.

The arteries of the antero-lateral wall are superficial and deep; the superficial epigastric and superficial circumflex-iliac from the femoral, the lower two intercostals from the thoracic aorta, the lumbar from the abdominal aorta, and ilio-lumbar from the internal iliac. Above are the superior epigastric and muscular-venous from the internal mammary—all forming the superficial set. Below are the deep circumflex-iliac and deep epigastric (inferior epigastric) from the external iliac. The latter is the most important and gives off the cremasteric artery, pubic and muscular branches. There is an anastomosis between the two lower epigastrics and between the deep epigastric and the internal mammary.

The veins are also divided into a superficial and deep set. Superficial are the superficial epigastric and superficial circumflex-iliac and another which passes subcutaneously along the side of the thorax, connecting above with the axillary vein and emptying below into either the superficial epigastric vein or into the femoral through the saphenous opening. It is dignified by the name Vena thoracico-epigastrica longa tegumentosa (Braune). The deep veins accompany their corresponding arteries and are usually double. The superficial veins do not
exactly correspond to their arteries, and are usually single. The superficial epigastric anastomoses with the deep epigastric, and both with the internal mammary.

Pressure upon the vena cava inferior forces blood into the superficial epigastric vein. A dilatation of the superficial abdominal veins to the size of the little finger (caput Meduse) may thus be caused by cirrhosis of the liver. This is explained by the anastomosis between the superficial epigastric vein and the portal system: the superficial veins communicate with the deep epigastrics and these with the portal system by means of a little vena parumbilicalis running in the falciform ligament of the liver.

Depending upon the seat of obstruction, whether in the vena cava inferior or in the portal system, the course of the blood-stream in the dilated veins may be in one of two directions: toward the umbilicus in the former case, and from it in the latter.

The deep veins are the vae comites of the deep epigastric and deep circumflex-iliac arteries. They communicate with the superficial set, the internal mammary, the portal system, and behind the sheath of the Rectus with a plexus in the parietal peritoneum.

The superficial lymphatic vessels above the umbilicus empty into the axillary glands, below the umbilicus into the inguinal glands. The deep lymphatics probably empty above into the sternal glands and below into the iliac glands.

The nerves supplying the whole musculature are the lower five intercostal, the anterior part of the first lumbar, viz. the ilio-hypogastric and ilio-inguinal. Twigs from the lower seven intercostal and from the ilio-hypogastric and ilio-inguinal furnish the sensory supply.
There may exist a congenital deformity in the anterior wall, a partial lack of development and an ununited symphysis pubis; with this the anterior wall of the bladder is lacking and its posterior wall, with ureters, exposed. This condition is called extrophy of the bladder.

The posterior wall of the abdomen proper has no special line of demarcation from the antero-lateral wall; its vertical length is of much less extent than the latter (Fig. 576).

It is the part into which the skeleton enters, composed of the five lumbar vertebrae connected by ligaments and disks. Laterally are the Psoas and Quadratus lumborum muscles, and behind these the Sacro-spinalis mass (Erector spinae muscle).

Through the lumbar region on either side of the vertebral column the following structures are met in order:

1. Skin.
2. Subcutaneous fascia and cellular tissue.
3. Lumbar aponeurosis, posterior layer.
4. Erector spinae muscle.
5. Transverse process and lumbar aponeurosis, middle layer.
6. Quadratus lumborum muscle.
7. Lumbar aponeurosis, anterior layer.
8. Psoas muscle.
10. Subperitoneal tissue and peritoneum.

This region presents the special districts, lumbar and iliac, already described. The arteries, veins, nerves, and lymphatics are all called lumbar.

The roof and floor of the abdomen are elsewhere described.

The apertures found in the walls of the abdomen for the transmission of structures to or from it are—the umbilicus, for the transmission (in the fetus) of the umbilical vessels; the caval opening in the Diaphragm, for the transmission of the inferior vena cava; the aortic opening, for the passage of the aorta, vena azygos, and thoracic duct; and the oesophageal opening, for the oesophagus and pneumogastric nerves. Below, there are two apertures on each side, one for the passage of the femoral vessels, and the other for the transmission of the spermatic cord in the male and the round ligament in the female.

The Abdominal Cavity and Contents.

It must be carefully noted that there is a difference between the abdominal cavity proper and the peritoneal cavity. The peritoneum does not closely cover everywhere the abdominal walls, but is pushed in and out, leaving spaces and diverticula so that some organs will be extraperitoneal, others intraperitoneal, yet all will be inside the abdominal cavity.

Before studying the peritoneum it will be best to become more familiar with the names and location of the important viscera. This can be shown in a topographical way by dividing off the surface of the abdomen into districts and considering the chief organs lying in each.

Regions.

Many authors have devised many means for this subdivision, all of which consist in allowing two horizontal planes to cross two perpendicular ones; the edges of these planes are indicated by lines on the abdomen. An old way was to let the edge of one horizontal plane intersect the anterior extremities of the ninth ribs, and to let the lower plane pass through the highest points of the crests of the ilia. The perpendicular planes passed each one through the centre of Poupart's ligament.

The advantage of the following method (Joessel) is that all its planes pass through bony points and its two perpendicular planes through the brim of the
pelvis. Here the highest plane is subcostal, passing just under the lowest margin of the thorax in a line drawn through the cartilaginous ends of the tenth ribs. The lower plane is interspinous and passes through the anterior superior spines of the ilia (Fig. 577).

This marks off three zones or regions: 1. Epigastric. 2. Mesogastric. 3. Hypogastric. Each one is again subdivided into three parts by the two sagittal planes which pass through on either side the ileo-pectineal eminence and end on the horizontal line connecting the tenth ribs (Fig. 578).

![Diagram of the abdominal cavity](image)

**Fig. 577.** Outline of the abdominal cavity as seen in mesial section. The planes of subdivision are indicated by dotted lines. (Cunningham.)

**Fig. 578.** Regions of the abdominal cavity. Anterior view. (Joessel.)

The epigastric zone contains, in order, the right hypochondrium (ἐπί, under: ἀντόμονα, cartilages), epigastrium (ἐπί, upon; γαστρόν, stomach) and the left hypochondrium. The mesogastric zone contains the right lumbar, the umbilical, and the left lumbar regions (the lateral regions may be called lateral abdominal). The hypogastric zone contains the right iliac, the pubic, and left iliac regions. Sometimes the iliac regions are called inguinal; then a subinguinal region is distinguished below Poupart's ligament.

The limits of the epigastric zone are the diaphragm above and below the horizontal plane through the anterior ends of the tenth ribs. The lateral and posterior limits follow the eleventh and twelfth ribs to end with the last on the
spinal column. The epigastric surface of this region is triangular, placed between the costal arches and horizontal line below. The transverse colon corresponds to this horizontal line. Somewhat higher, opposite the ninth rib, is the greater curvature of the stomach in moderate distention. In the middle of the epigastrium farthest above is a depression called the *gastric or cardiac fossa* (*scrobiculus cordis*); corresponding to this place is the liver and pyloric end of stomach.

The *hypochondriac regions* include the spaces between the diaphragm superiorly, posteriorly, and externally, the costal cartilages internally, and the horizontal plane below. The right one is filled by the liver. The left one contains the spleen, the splenic flexure of the colon, the greater part of the stomach, and after distention of the stomach a large part of the great omentum.

![Diagram of the abdominal cavity](image)

**Fig. 579.—Regions of the abdominal cavity. Posterior view. (Joessel.)**

The *mesogastric zone* is bounded above by the epigastric zone and below by the horizontal plane passing through the anterior superior spines of the ilia. Laterally and behind are the crests of the ilia. In the umbilical region lie the great omentum, the loops of small intestine, and their mesentery. In the lumbar regions, which extend from the perpendicular lines drawn through the ileo-pectineal eminences around to the vertebral column, are also small intestines, the kidneys, the ascending and descending colons.

The *hypogastric zone* is bounded above by the mesogastric and below by the brim of the true pelvis. The *pubic region* in the centre contains the bladder, the right iliac, the cecum, and the left iliac, a part of the sigmoid flexure.
THE ORGANS OF DIGESTION.

To recapitulate:

**Right Hypochondrium.**
- Liver.

**Epigastrium.**
- Liver.
- Stomach.

**Left Hypochondrium.**
- Greater part of stomach.
- Spleen.
- Splenic flexure of colon.
- Great omentum.

**Right Lumbar.**
- Right kidney.
- Small intestines.
- Ascending colon.

**Umbilical Region.**
- Great omentum.
- Small intestines.
- Mesentery.

**Left Lumbar.**
- Left kidney.
- Small intestines.
- Descending colon.

**Right Iliac.**
- Caecum.

**Pubic.**
- Bladder.

**Left Iliac.**
- Part of sigmoid flexure.

Fig. 579 gives a posterior view of the abdominal cavity, showing a vertebral region and the two lateral regions of the mesogastric zone continued posteriorly, the right and left lumbar. There are to be seen the outlines of the kidneys, the spleen, the ascending and descending colons. The dotted line meeting the vertebral column at the eleventh rib is the lower lung limit; the line at the twelfth rib is the lower pleural limit. The vertebral region includes the vertebral column and part of the Quadratus lumborum muscles.

THE PERITONEUM.

Let us now suppose the student has finished the dissection of the anterolateral abdominal wall, has studied the anatomy of inguinal and femoral hernia, the sheath of the Rectus muscle, and has seen the adminiculum linea albae. The semilunar folds of Douglas are before him, and he is ready to incise the transversalis fascia and the parietal peritoneum.

The Recti muscles should have been cut transversely a little below the umbilicus and both turned-down together from their sheath without dividing the linea alba.

![Diagram of the Recti abdominis muscles](Luschka.)

Behind the Recti on the lower and posterior part of the linea alba is a triangular band of fibrous tissue called adminiculum linea albae (adminiculum, "prop on which a vine grows") (Fig. 580, 4). It passes up 4 or 5 cm. to strengthen the
white line, its apex being above and its base below. It rises from the crests of the pubic bones and arches over the upper edge of the symphysis pubis. This should not be mistaken for the urachus which lies behind it, separated by the transversalis fascia; both are outside the peritoneum.

Now open the peritoneal cavity. Do not make a median incision from the ensiform cartilage to the symphysis pubis. Start at the umbilicus and make two oblique cuts from it, one to each Poupart's ligament near the anterior superior spine of the ilium; make one more from the umbilicus to the ensiform cartilage. Make a transverse cut on either side when more room is desired. To the right of the upper incision will be seen a round cord passing from the umbilicus to the under surface of the liver and enclosed in a double layer of serous tissue. The latter is peritoneum, called the broad, suspensory, or falciform ligament of the liver; the cord is the round ligament of the liver, or a part of the obliterated umbilical vein, which in the fetal state carried arterial blood from the placenta to the liver first and thence over the body.

Turn down the lower triangular flap and the view presented is shown in Fig. 581. Three distinct bands or cords are seen passing from below upward toward the umbilicus. They are all foetal structures. The middle one is the urachus, the remnant of the stalk of the allantois; it may remain pervious. The two lateral ones are the obliterated hypogastric arteries which conveyed venous blood

---

Fig. 581.—Posterior view of the anterior abdominal wall in its lower half. The peritoneum is in place, and the various cords are shining through. (After Joessel.)
from the fœtus to the placenta for oxygenation which was returned, as we have seen, by the umbilical vein. The younger the subject under dissection, the bigger are these two cords. Near the umbilicus they subdivide into numerous threads which in part join the urachus, in part run free toward the umbilicus, and only the smallest part reaches it. The proximal part of this artery is still pervious after birth as far as the bladder under the name of superior vesical.

To either side of the three cords is seen the deep epigastric artery passing in behind the Rectus at the semilunar fold of Douglas. These five bands are covered posteriorly by peritoneum, which is thrown backward in five folds or ridges (plica, fold) forming in all six fossæ, or three to a side. Sometimes the obliterated hypogastric artery is identical in position with the deep epigastric, in which case folds and fossæ are less in number. The middle fold is called plica umbilicalis media or superior ligament of the bladder; the next on either side the plica umbilicalis lateralis, or lateral ligament of the bladder; the fold over the deep epigastric artery is the plica epigastrica. The simplest nomenclature is plica urachi, plica hypogastrica, plica epigastrica. The fossæ included between these folds are named—the most external, outside the epigastric artery and above Poupart's ligament, the external inguinal fossa; between the urachus and the cord of the obliterated hypogastric artery is the internal inguinal fossa, and the remaining depression is the middle inguinal fossa. This one may be very narrow and quite deep. The external fossa has on its floor the internal abdominal ring, and admits the oblique inguinal hernia; either of the other two allows a direct inguinal hernia. To the inner side of the femoral vein is the femoral or crural fossa, the site of femoral hernia. All the above points should be noticed when the abdomen is opened.

The structures now presented for study, more or less preliminary at first and in detail later, are here presented.

1. Peritoneum which lines the cavity and clothes the viscera.
2. Abdominal part of alimentary canal:

   (Duodenum.
   Small Intestine Jejunum.
   Ileum.
   Large Intestine Cæcum.
   Ascending colon.
   Transverse colon.
   Descending colon.
   Sigmoid Flexure.
   Rectum.

3. Accessory Glands Liver.
   Gall-bladder.
   Pancreas.

4. Spleen.
5. Two Kidneys, Ureters, Adrenals or Suprarenal Capsules, and Bladder.
6. In female, Uterus, Ovaries, and Fallopian Tubes.
7. Lymphatic Glands, Vessels, and beginning of Thoracic Duct.
8. Abdominal Aorta and nine sets of branches.
9. Vena cava inferior and tributaries; beginning of Vena azygos major and minor.
11. Lumbar Plexus of cerebro-spinal nerves; Sympathetic Nerves and Plexuses.

We get but a partial view of all when the viscera are undisturbed (Fig. 584). Like a curtain the great omentum conceals most of the small intestines, but it may be short or turned up to or one side. The parts to be seen are indicated in the diagram. To find the transverse colon, throw the great omentum and stomach well up over the ribs; now the whole colon can be traced, beginning in the
THE PERITONEUM.

right iliac fossa at the caecum, then upward, across, downward, and into the sigmoid flexure and rectum. This surrounds the coils of the small intestines.

The other structures not evident without dissection or manipulation can be located by aid of Figs. 582, 583. The organs there are all spaced and so are not in their exact positions.

It is customary to study the peritoneum before taking up the separate visera. This membrane has quite a reputation. Whenever in Human Anatomy anything is difficult or obscure, one should leave the complex adult form and study the more primitive simple type of the embryo or new-born; if that be not wholly satisfactory, go to the lower animals (Comparative Anatomy), while the ambitious student investigates even fossil animals (Paleontology). It is meant by this that the medical student should first study something of the development of the peritoneum before opening the abdominal cavity and destroying important structures.

Some Essential Facts in the Development of the Peritoneum.

In the early development of the alimentary canal, before the twelfth day in the human embryo, all three germ-layers push forward, are folded over, and produce the head and the anterior part of the fore-gut. This is blind at the front end, and the mouth is developed later by an invagination from the exterior. The middle part of the future alimentary tract, mid-gut, is in free communication for some time with the blastodermic vesicle which is later called the yolk-sac. The approximation of the body-walls at the umbilicus gradually pinches the yolk-stalk off into the vitelline duct, so the sac finally lies wholly outside the body of the
embryo and that part of it enclosed within is the pleuro-peritoneal cavity (Fig. 585). Finally, at the caudal end a hind-gut is formed and an anus added by a process of invagination.

Thus the whole alimentary canal was originally a straight tube placed in front of the aorta, or the original two primary aortae, and that in front of the future vertebral column, the chorda dorsalis (Fig. 586). Along its middle region, the anterior wall is lacking as it opens here into the yolk-sac.
The fore-gut contracts to form the *oesophagus*, which is very short (Fig. 587). This gradually widens into a spindle-like dilatation indicating the *stomach*. The *small intestine* is short and straight with a wide opening into the yolk-sac. Just below the stomach, the liver is budding out from the duodenum. This stage is attained in the fourth week in the human embryo. There are now five successive
districts in the whole canal, mouth, throat and visceral clefts, esophagus, spindle-shaped stomach, and the remaining tube connected with the yolk-sac.

By the fifth or sixth week, the stomach, at first straight and parallel with the axis of the body, begins to show a convex greater curvature toward the vertebral column and a concave lesser curvature on the opposite side. This is covered by the voluminous liver. The pyloric end is tilted away from the column and this forms the duodenal loop (Fig. 588). As the communication with the yolk-sac becomes constricted and absorbed there is developed a long umbilical loop of intestine opposite the vitelline duct. The end of this loop passes for a time into the umbilical cord surrounded by a protrusion of the peritoneum. This loop passes downward and forward, and consists of two nearly parallel arms between which is stretched the mesentery. At a little distance from the vitelline duct on the lower arm of the loop is seen a small enlargement; this marks the future cecum and beginning of the colon and end of small intestine. Five portions of intestine are now to be distinguished: the short part passing back from the stomach toward the spinal column becomes duodenum; at the turning-point into the umbilical loop is the duodeno-jejunal junction; the anterior descending arm and bend of the loop become small intestine; most of the ascending posterior arm becomes colon, and the terminal part, sigmoid flexure and rectum.

At first the alimentary tract is mostly in contact with the chorda dorsalis held by a broad mass of embryonal connective tissue. This tissue contains two

primitive aortae. The right and left portions of the body-cavity approach each other and compress this tissue into a mesentery, which is attached to the whole length of the tube beginning with the stomach, connecting it with the chorda. The special part of this membrane attached to the stomach posteriorly is called mesogastrium, that to the small intestine is called mesentery (medium intestinum
or μέσων σύντερπος, middle intestine); that to the colon, the mesocolon; that to the sigmoid flexure, the mesosigmoidia or sigmoid mesocolon; and that to the rectum, the mesorectum. This has not been represented in the above figures for the sake of simplicity. There is also a ventral mesentery, but not of such extent as the dorsal. It extends along the front of the alimentary canal from the throat to the lower end of the duodenum and in front as far down as the umbilicus (Fig. 589). It almost makes the body-cavity a paired structure. In the upper part of this mesentery is developed the heart, the part enclosing it being called mesocardium anterius and posterius. The lower part extends from the stomach and duodenum to the anterior wall and has many names—ventral gastric and duodenal mesentery, liver-ridge and prohepaticus; it is never called anterior mesogastrium.

The liver is here developed anterior to the stomach, budding from the anterior part of the beginning of the duodenum (Fig. 590).

The pancreas buds from the posterior part of the duodenum, vertical at first and covered on both sides by the mesentery of the small intestine; it passes into the mesogastrium later and becomes transverse.

The spleen is developed in the second month in the mesogastrium and is not connected directly with the alimentary canal.

At this stage, passing from before backward, we find the structures arranged: anteriorly, liver; in the centre, stomach; posteriorly, spleen and pancreas. The anterior mesentery in front of the liver becomes the suspensory or falciform ligament of the liver, extending to the umbilicus below and embracing the intra-abdominal part of the umbilical vein. The anterior mesentery between the liver and stomach becomes the lesser omentum or lig. hepato-gastro-duodeneale. The mesogastrium between stomach and spleen becomes gastro-splenic omentum, and that part between the spleen and vertebral column forms the great omentum.

Fig. 591 is a cross-section of the same embryo. Anteriorly are the two sacs of the liver projecting one into each side of the body-cavity. The right sac grows to a larger size than the left; they form respectively the right and left lobes. Behind these is the duodenum and behind that the pancreas. The intervening parts of the mesentery are called ligaments, viz. first, suspensory ligament of liver, next hepato-duodenal ligament, next duodeno-pancreatic ligament, and lastly the dorsal mesentery. Note that pancreas and duodenum are wholly enclosed.

The vascular arrangement of this stage is shown in Fig. 592. The celiac axis, the superior mesenteric and inferior mesenteric arteries have their points of supply definitely marked out even in the sixth week. They pass from the aorta between the two layers of the mesogastrium and mesentery to their destinations, which never change. The celiac axis goes to the stomach, spleen, pancreas, liver and part of duodenum; the superior mesenteric, to part of duodenum, the
small intestines, and part of colon; the inferior mesenteric, to the remainder of the tube.

The length of the intestine continually increases, and it becomes more bent and tortuous, till from the third month on there occur two important changes, one in regard to a twist of the intestinal loop and one in regard to a change in position of the stomach. The ascending and descending arms of the umbilical loop have been lying side by side one above the other; now the lower arm, which becomes cæcum and colon, begins to pass over the upper arm and crosses the small intestine transversely (Fig. 593). The upper arm moves but little or none, as it is already fixed to the vertebral column at its upper duodeno-jejunal end, perhaps by the muscle of Treitz.

The cæcum, which has already developed an appendix, is thus landed wholly on the right side of the body up under the liver (Figs. 594 and 596). At first there is no ascending colon, the transverse colon running across the duodenum inferior to the stomach and up to the spleen, making a splenic flexure; it passes through
the left lumbar region and is continued into the sigmoid flexure and rectum. The cecum increases in length and, finding least resistance below, finally settles into the right iliac fossa, dragging down a short ascending colon.

The mesentery, seen in the loop of Fig. 592, makes a half rotation as does the loop, and its anterior surface becomes posterior, as may be inferred from Figs. 595 and 596.

Fig. 597 shows the arterial supply after the twist of the umbilical loop, with the celiac axis behind the stomach, the superior mesenteric artery fastening the duodenum between itself and the aorta, and the inferior mesenteric coming off below.

During this period of intestinal torsion, the stomach has suffered a double change. First the stomach twists around an antero-posterior axis, so its cardiac or esophageal end moves to the left and downward, while its pyloric end moves a little to the right and upward; and its vertical position becomes more transverse.

Secondly, its long axis having been parallel to the vertebral column, it originally presented a right and left surface, supplied respectively by the right and left vagus nerves. It now falls over so that its right side becomes posterior and its left side anterior, and the greater curvature becomes more inferior, and the lesser curvature more superior. The vagus nerves still supply the same surfaces, which have changed their positions: the right nerve now goes to the posterior surface and the left one to the anterior surface.

The lower end of the esophagus also experiences the same torsion.

The mesogastrium is modified by this rotation to the right. In the anterior mesentery is the liver (Fig. 590), but in the adult we find it shifted to the right side of the body. The spleen was posterior to the stomach; in the adult it is to its left. So these three antero-posterior organs have become laterally placed, and from right to left are hereafter found: liver, stomach, spleen.

Again connected with this torsion of the stomach is associated the formation of the great omentum. To illustrate this, carve a piece of wood to represent the
stomach; let two layers of cloth attached to the posterior border represent the mesogastrium attached to the vertebral column (Fig. 598). This was the original condition (Fig. 592). Now turn the stomach to the right, allowing the cloth to fall loosely to the left, and immediately a cavity is formed included between two layers of cloth anteriorly and two layers posteriorly (Fig. 599). In the embryo a similar cavity is formed called the cavity of the great omentum, the lesser sac of peritoneum, bursa omentalis; and a similar fold of four layers is formed called the great omentum which in the embryo and infant contains this cavity.

The entrance to this cavity is indicated by the arrow in Figs. 595, 596, and 599, and the bulging of the great omentum is seen to the left of and below the greater curvature of the stomach. Compare the above with Fig. 600, and the position of the sac will be better understood.

The front wall of the bursa omentalis is formed by the stomach; the posterior wall by the mesogastrium, which at first completely invests the pancreas, touches the spleen, and covers part of the left suprarenal capsule. The opening is turned to the right and covered anteriorly by the lesser omentum. The space between

![Fig. 600.—Schematic and enlarged cross section through the body of a human embryo in the region of the mesogastrium. Beginning of third month. (Toldt.)](image)

![Fig. 601.—Same section as in Fig. 600, at end of third month. (Toldt.)](image)

the lesser omentum and right end of pancreas is the atrium bursae omentalis or the antechamber or lesser omental pocket. It lies below and behind the Spigelian lobe of the liver. The bursa proper, or lesser sac, is that part behind the stomach.

By the end of the third month the pancreas touches the left suprarenal capsule (Fig. 601), the layer of mesogastrium separating the two becomes later absorbed, and the pancreas is then an extraperitoneal organ separated from the kidney or capsule by connective tissue. By further development this lesser sac continues to push between the layers of the great omentum downward and to the left, and fuses with neighboring viscera. The great omentum, formerly a part of the mesogastrium, comes to hang freely down over the transverse colon and then in front of the small intestines, as about to do in Figs. 596 and 602.

The lamellae composing the bursa omentalis or lesser sac are each composed of two layers; they are placed close together and are continuous below (Figs. 602 and 603). The more anterior one is attached to the greater curvature of the stomach and the posterior one lying on the intestines was originally attached to the vertebral column and enclosed most of the pancreas (Figs. 600 and 602). In many mammals no further change occurs. In man fusions follow: the pos-
terior lamella covers a large part of the posterior abdominal wall, and its original line of vertebral attachment gets displaced to the left; it joins the diaphragm and forms the lig. phreno-lienale, suspensory ligament of the spleen. Below it becomes fused to the upper layer of the transverse mesocolon and to the transverse colon (Fig. 603). These two contiguous layers, i.e., the posterior layer of the mesogastrium and the upper layer of the transverse mesocolon, may present a fissure at birth in many mammals. During early infancy in the human species they form a single lamella with a deposit of fat (Fig. 603). In adult life no trace of the extra layer is seen.

There are then three types of relation of the posterior layer of the great omentum to the transverse mesocolon: fetal, where they are separate (Fig. 602); infantile, where they are fused into one layer (Fig. 603); and adult, where all trace of this layer has disappeared and the posterior lamella of the great omentum seems to enclose the transverse colon (Fig. 606).

The lesser sac of peritoneum (bursa omentalis) is still continuous with the greater sac or general peritoneal cavity, something like the two cavities of an hour-glass, only the upper cavity (lesser sac) is comparatively small and bent down behind the other. In Fig. 603 the cavity behind the stomach is connected with the larger cavity in front of it by means of a foramen to the right of the lesser omentum. It is the foramen of Winslow, and is to be found just under the hilus (the black spot on a bean) of the liver to the right side of the neck of the gall-bladder.

After childhood the cavity of the lesser sac descending into the great omentum is obliterated and the four layers are fused into an omental plate.
Mesentery of the Small Intestine and Colon.

The mesentery is influenced by the increase in length of the small intestine. It becomes fan-shaped, and its length at its insertion into the intestine is many times that of its origin from the lumbar vertebrae; so it lies in folds and is called a frill. In man after the fourth month, this becomes more complicated by fusions with the posterior body-wall or neighboring viscera. It affects especially the mesentery of the duodenum and colon.

The duodenum at first is completely invested with peritoneum (Fig. 595); later other viscera growing faster are thought to pull it away and appropriate it, and so posteriorly it comes to lie on the posterior wall of the body and becomes an immovable organ (Fig. 603).

The large intestine possesses a suspensorium attached to the vertebral column and designated the mesocolon. When the twist of the umbilical loop occurred, the transverse colon and its mesocolon were drawn transversely across the duodenum, and a new secondary line of attachment was thus formed. This explains why in the adult we find the body-cavity divided by the transverse colon and transverse mesocolon into chambers, an upper and a lower. In the upper are the stomach, liver, pancreas, spleen and part of duodenum; in the lower, part of duodenum and the small intestines. The duodenum, in order to get from the upper to the lower space, passes underneath the transverse colon or apparently through the mesocolon (Fig. 596).

The cæcum, ascending and descending colon, also lie with their posterior walls more or less in contact with the body-wall, but sometimes they have a more or less distinct mesentery as they did originally. The original disposition can be seen by taking a cross section of the alimentary canal in Fig. 596 along the line X. Each colon and the small intestine are fixed to the aorta and vertebral column by its special mesentery, which allows freedom of motion (Fig. 604). The mesentery is seen to be formed of two layers of peritoneum which surround an intestine completely, except at a posterior line where there is opportunity for

---

**Fig. 604.**—Cross section of alimentary canal of Fig. 596 to show mesenteries. (Dexter.)

**Fig. 605.**—Schematic drawing of a cross section of a serous cavity. (Gegenbaur.)
vessels, nerves, and lymphatics to enter or return. Two layers of peritoneal connective tissue, which lodge vessels, nerves, and lymphatics, constitute a mesentery. The intestine looks as though it had pushed its way into the sac of peritoneum as a finger enters a glove. That comparison is incorrect, for intestine and peritoneum are developed simultaneously. The intestine is not first made and then pushed, as would appear (Fig. 605).

The intestine and the two layers of peritoneum are formed together. As the intestine recedes, the serous membrane comes from the wall to it in a duplicature. The layer covering the intestine is called visceral; that reflected upon the parietes or wall is the parietal layer, and the passage from one to the other is the mesentry.

In the adult the small intestine is unchanged, but the mesentery of the right and left colon has been widely separated posteriorly, and it and some of the parietal peritoneum have been changed to connective tissue, so each colon becomes fixed and partly extraperitoneal, like the duodenum and pancreas (Fig. 603). The kidneys were always outside, being developed in the retroperitoneal space.

Summary.

Separation of the alimentary tube and its mesentery into distinct regions (Hertwig):
1. The alimentary canal is originally a straight tube from mouth to anus, near the middle of which the yolk-sac is attached by the vitelline duct (Figs. 586 and 587).
2. The alimentary tube is attached throughout its whole length to the vertebral column by a narrow dorsal mesentery; it is also connected with the anterior wall, as far as the umbilicus, by means of a ventral mesentery.
3. At some distance behind (below) the visceral clefts, the stomach arises as a spindle-shaped enlargement; its dorsal mesentery is designated as mesogastrium.
4. The portion which follows the stomach grows more rapidly in length than does the trunk, and therefore forms a loop with an upper, descending, narrower arm, which becomes the small intestine, and a lower ascending more capacious arm which produces the large intestine.
5. The stomach takes on the form of a sac and becomes so turned that its long axis coincides with the transverse axis of the body and that the line of attachment of the mesogastrium, or its greater curvature, which at first was dorsal, comes to lie below or caudad.
6. The intestinal loop undergoes such a twisting that its lower ascending arm (large intestine) is laid over (ventrad to) the upper descending arm (small intestine) from right to left and crosses it near its origin at the stomach.
7. The twisting of the intestinal loop explains why in the adult the duodenum, as it merges into the jejunum, passes under the transverse colon and through its mesocolon (crossing and crossed parts of the intestine).
8. The lower arm of the loop, during and after its twisting and crossing of the upper arm, assumes the form of a horseshoe, and permits one to distinguish the cecum, the colon ascendens, colon transversum, and colon descendens.
9. Within the space bounded by the horseshoe, the upper arm of the loop becomes folded to form the convolutions of the small intestine.
10. The mesentery, which is at first common to the whole tube, becomes differentiated into separate regions and adapts itself to the different folds and elongations. It is elongated and here and there undergoes fusion with the peritoneum of the body-cavity, by means of which it acquires new points of attachment, or in certain tracts wholly disappears; some portions of the intestine are thus deprived of their mesentery (Fig. 614).
11. The mesentery of the duodenum, and in part that of the colon ascendens and descendens, fuses with the wall of the body.
12. The mesentery of the colon transversum acquires a new line of attachment running from right to left, and becomes differentiated from the mesentery as mesocolon.

13. The meso-ogastrum of the stomach follows the torsions of the latter, and is converted into the greater omentum, which grows out from the greater curvature of the stomach to cover all the viscera lying below.

14. Fusion of the walls of the omentum occur with the adjacent serous membranes: (1) on the posterior wall of the body, where its line of origin from the vertebral column is displaced to the left side of the body (Fig. 614); (2) with the transverse colon and mesocolon (Fig. 603); (3) anterior and posterior walls come into close contact and fuse into an omental plate.

Development of special organs out of the walls of the alimentary tube:

1. From the intestinal canal proper there are formed only two glands, developed from the duodenum, viz. the liver and pancreas.

2. The liver is developed as a branched tubular gland which becomes a network: (a) There grow out from the duodenum into the ventral mesentery or pre-hepaticus two liver-tubes, the fundament of the right and left lobes of the liver. (b) The tubes form hollow or solid branches, the hepatic cylinders, which become in part bile-ducts and in part parenchyma of the liver. (c) The common bile-duct rises as an evagination of the wall of the duodenum receiving the two hepatic tubes, and at one place an evagination which becomes the gall-bladder and cystic duct.

3. From the ventral mesentery into which the liver grows are derived the suspensory ligament of the liver (falciform) and the lesser omentum.

4. The pancreas grows from the duodenum into the dorsal mesentery and into the meso-ogastrum.

The mesentery, which the pancreas originally possesses, disappears and fuses with the posterior body-wall. By reason of the twist of the stomach, the long vertical axis of the pancreas becomes transverse.

Adult Peritoneum.

During life and before dissection of the dead subject the abdominal cavity is air-tight. Atmospheric pressure and muscular tension allow no space to be vacant. The peritoneum (περιτοινέαν, to extend around) is the shiny serous membrane lining the abdominal walls and posteriorly either lining the wall or covering the viscera. If one is asked to touch the liver or stomach it is the peritoneum covering those organs which is touched. The peritoneal cavity was opened when the anterior abdominal wall was incised, and does not exist till artificially produced by the surgeon or dissector.

In the male it is a closed sac with its two walls approximated, and consequently perfectly empty except for a small amount of yellowish-green lubricating fluid, liquor peritonei. Its anterior wall has already been opened and is called the parietal peritoneum. Its posterior wall is tucked into every crevice and corner around and between the viscera, which may be regarded as lying behind the whole sac. This layer is largely visceral and the spaces between single organs are only capillary. In the female, the peritoneum has two openings; there is a single region on either side where mucous membrane is continued into serous membrane, viz. where the Fallopian tube opens into the peritoneal cavity.

Other serous membranes are comparatively small, and, like the pleura, serous pericardium, or tunica vaginalis, surround one organ. In these it is very easy to trace the layer around the walls, then its reflection upon the viscera and off again to the starting-point. In the peritoneum, or really behind it, we have many organs involved, nearly all of which have experienced changes in size or position during fetal life, so that the task is somewhat more complex. It is to trace the peritoneal layers from one organ to another or from an organ to a wall, and to show that the layers are continuous, making a closed sac.
THE PERITONEUM.

We may say that the peritoneum has two surfaces, i.e., one attached to the wall or viscus and the other is free and shiny; there are two layers, parietal and visceral, and two sacs, since the large one has a posterior subdivision formed when the stomach rotated to the right in the embryo.

The various folds and bands formed by the peritoneum in passing from the different viscera or walls have definite names.

An Omentum means a fold of peritoneum which connects the stomach with other viscera, viz. great and gastro-colic omentum, small or gastro-hepatic, and gastro-splenic. These are situated respectively below, above, and to the left of the stomach.

A Mesentery is a fold of peritoneum connecting any part of the small intestine to the posterior wall. It is used also in a wider sense. The name of the fold connecting any part of the alimentary canal below the oesophagus to vertebral column or posterior abdominal wall may be found by prefixing the Greek adjective mesos (μεσος) or Latin medium to the Greek or Latin name of the part fixed, as mesogastrium, mesoduodenum, mesentery, mesenteriolium (little mesentery for vermiform appendix). There is no mesocecum in the adult, but sometimes an ascending or descending mesocolon; always a transverse mesocolon, a sigmoid mesocolon, and a mesorectum.

Ligament is a term applied to folds connecting viscera not belonging to the intestinal canal, to the abdominal walls, or to folds which bind viscera to the diaphragm. The German anatomists apply this term also to omenta. There are ligaments of the bladder, uterus, and liver, and others, as lienorenal, hepatorenal, and gastro-phrenic.

We will now trace the peritoneum in a vertical direction simply to show its continuity and to see from a side view how it surrounds viscera or forms bridges from one organ to another (Fig. 606).

We may begin anywhere, perhaps best at a point above the liver, where the parietal layer of peritoneum is reflected from the diaphragm to the liver, becoming visceral layer.

The student is supposed to have read carefully all the description of the peritoneal development. Now he follows by hand the parts in the subject and the diagram by eye. Lifting up the diaphragm the hand passes over the glistening superior surface of the liver in the middle line till it is stopped posteriorly by a fold called the coronary ligament. The peritoneum covers all the surface of the liver to its anterior acute margin. Next lift up the liver from the stomach and trace the layer backward on the under surface of the liver to the transverse fissure or hilus, and the hand is again stopped, this time by the peritoneum descending to the lesser curvature of the stomach, making one layer of the lesser omentum; or, giving the names of the viscera connected, hepato-gastric omentum. This layer now covers the anterior surface of the stomach and reaches the greater curvature; here it falls directly downward to a varying extent, usually to the public region, making the anterior superficial layer of the great omentum. Just below the stomach the transverse colon may be seen shining through. This layer in the foetus and young child should not be attached to it, however. Now lift up the great omentum over the stomach and this layer may be seen to be reflected up to the under surface of the transverse colon, making the posterior superficial layer of the great omentum. Fig. 602 shows that the great omentum has not always been present; this layer we are now tracing used to pass above the transverse colon and go to the pancreas and then return, making two layers. Fig. 603 shows how these two layers united into one; and Fig. 606 shows how one has disappeared as such, and how this layer passes beneath the transverse colon and on to the vertebral column and anterior margin of the pancreas, making the lower layer of the transverse mesocolon.

This layer is closely connected with the vertebral column, aorta, and vena cava inferior, and on leaving the pancreas meets the superior mesenteric vessels and surrounds them. It covers only anteriorly the pre-aortic portion of the duode-
num, and makes another excursion to surround the small intestines and returns under the vessels forming the two layers of the mesentery proper. (Take a definite portion of the small intestine and prove this—that the mesentery has an upper and a lower layer and the intestine is fastened to the spinal column by it.)

Next, this layer descends into the pelvis and forms a mesentery for the intestine, there surrounding it as low down as the middle of the third sacral vertebra. If anatomists agree to call that intestine the upper part of the rectum, the fold is mesorectum, but if the intestine be called the lower part of the sigmoid flexure, the fold is sigmoid mesocolon, and there is no mesorectum. Just at the third sacral vertebra the peritoneum leaves the posterior surface of the intestine, then the sides, and then the front, and is reflected in the female next upon the upper fifth
or fourth of the posterior wall of the vagina and then upon the uterus, covering its posterior wall, its fundus, its anterior surface, but it does not pass on to the vagina in front. About the level of the internal os it passes over the summit of the bladder as far as the urachus. The deep pouch behind the uterus and vagina is called the recto-vaginal pouch, or cul-de-sac of Douglas, or recto-uterine pouch. The more shallow anterior pouch is the vesico-uterine. In the male the peritoneum passes from the rectum directly upon the posterior wall and summit of the bladder to the urachus, forming behind the recto-vesical pouch. In either sex the peritoneum passes directly from the bladder to the anterior abdominal wall and does not cover the bladder anteriorly. The surgeon makes use of this fact in operating upon the bladder through this space below the peritoneum and above the symphysis pubis. It is called the pre-vesical space of Retzius, and is much increased in size by distending the bladder. By putting 420 c.c. of fluid into a rubber bag in the rectum and 500 c.c. into the bladder, the rectum will so push up the bladder and the bladder will so push up the peritoneum that a space of 8.5 cm. will exist between the lowest fold of peritoneum and the symphysis pubis.

This parietal layer is then simply traced, lining the anterior abdominal wall around to our starting-point between the liver and diaphragm. We see then that this is a closed sac and the parietal layer is continuous with the visceral. This is the cavity of the greater peritoneal sac.

We have not yet brought the peritoneum into contact with the Spigelian lobe of the liver or the posterior surface of the stomach or internal surface of the spleen. Behind the upper part of the large cavity and running into its lower part is another artificial cavity which we have not traced, viz. the cavity of the lesser sac, or the bursa omentalis. We have seen that these two sacs are, continuous with each other through the foramen of Winslow. That is best shown in a cross section, but is indicated in the diagram.

The boundaries of the lesser sac cannot be well seen at this stage, and for the present must be mostly studied by diagram till the anterior parts are dissected. Remember the diagram is only true for the median line or near it, and nowhere else but in the region of the Spigelian lobe of the liver does the lesser sac reach up behind it as here represented. Imagine the hand introduced through the foramen of Winslow from right to left into the lesser sac; push the finger up behind the liver and in front of the diaphragm till stopped by the fornix made by the transition of parietal to visceral layer. This layer invests the Spigelian lobe only behind and inferiorly till the transverse fissure is reached; it then descends, as did the layer of greater sac in front of it, to the lesser curvature of the stomach forming the posterior layer of the lesser omentum. Next it descends behind the stomach and in front of the transverse colon into the great omentum, passing nearly to the free border of that apron. It now turns and ascends and covers the upper surface of the transverse colon and goes back to the vertebral column, forming the superior layer of the transverse mesocolon. It now covers the anterior surface of the pancreas, next the vertebral column and crura of diaphragm and great vessels to the reflection on to the liver.

It is advised that the above tracings for both sacs be followed in Fig. 607, which represents the organs in greater detail. This diagram shows two sections of the duodenum, one in its first and one in its second portion. A median section would show its third portion about at the root of the mesentery (Fig. 606).

We have traced the layers singly, and some new features may be presented if we take two layers together, beginning above at the liver.

Anteriorly, a layer passes back under the diaphragm and from behind another approaches it; one is from the greater sac and the other from the lesser (if section be near median line). They both turn down upon the liver, making these the anterior and posterior layers of the coronary ligament, including between them a small surface of liver directly connected to the diaphragm and uncovered by peritoneum. These two layers then surround the liver, forming its serous coat, and meet again at the transverse fissure. The two now descend to the
lesser curvature of the stomach, forming the lesser omentum or hepato-gastric omentum, the right free margin of which, also made of two layers, is called the *lig. hepato-duodenale*, because it passes between liver and duodenum. Between the two layers of this ligament to the right are the common bile-duct, the hepatic artery, and portal vein, all surrounded by connective tissue, the *capsule of Glisson*. These layers next invest the stomach, meeting at its greater curvature. They next pass down in front of the transverse colon and small intestines and form the anterior lamella of the great omentum; they turn on themselves and

reach the transverse colon, forming the posterior lamella of the great omentum, and next surround the transverse colon. Then they pass to the vertebral column, forming the transverse mesocolon with its upper and lower layers, and covering the anterior and inferior surfaces of the pancreas by their bifurcation, one layer passing upward and the other downward. These layers now diverge to complete their respective sacs, which have been traced, and meet again as the coronary ligaments of the liver at the starting-point.
So far we have seen the reflections and pouches in a longitudinal section in or near the median line.

It is the arrangement as found in the infant up to the age of two years; after that age the great omentum does not usually show a cavity.

We should next trace the peritoneum transversely in cross sections. This is simplest low down in the abdomen, where only the greater sac is involved. Let the section be made through the lumbar region somewhat above the level of the umbilicus (Fig. 608). Beginning at the linea alba, trace the parietal layer around to the right until it nearly reaches the outer border of the Quadratus lumborum muscle. It then passes up over part of the anterior surface of the right kidney and meets the ascending colon. It partly surrounds it, forming sometimes a proper mesocolon, but usually leaving one-third of the posterior surface exposed. At birth only the anterior and external surfaces are covered.

This layer then passes from the right kidney over the Psoas muscle, over the vena cava, and, meeting the superior mesenteric vessels from the side, is led by them to surround the small intestine, enclosing blood-vessels, lacteals, lymphatics, and nerves in the mesentery proper. It next passes over the vertebral column and aorta, anterior to the left Psoas muscle and left kidney, and covers the anterior surface and sides of the descending colon, forming sometimes a true descending mesocolon. It next is reflected upon the antero-lateral abdominal wall and is continuous with itself at the linea alba.

Notice that the lower end of each kidney may be best felt by palpating to the right of each colon.

By taking a cross section higher up, just above the transverse colon, both cavities are involved, making the tracing more complex, but the continuity of one with the other is well seen. The spleen is met in this section, and all parts of the colon are below (Fig. 609). Begin again in front at the linea alba and trace to the right; soon the layer makes a fold open to the front and encloses the obliterated umbilical vein, now called the round ligament of the liver. The fold is a part of the fotal anterior mesentery, now called falciform or suspensory ligament of the liver. The layer is a parietal one, passes to the posterior abdominal wall and covers the anterior surface of the right kidney and then passes in front.

---

**FIG. 608.—Peritoneal reflections in a transverse section of lumbar region below transverse colon. Seen from above. Schematic. (From Tillaux.)**
of the vena cava and behind the margin of the hepato-duodenal ligament which is the right free edge of the lesser omentum. This layer now forms the posterior wall of the lesser sac and is directly continuous with the layers of the greater sac.

It passes over the vertebral column, the crura of the diaphragm and great vessels, in front of the left kidney to the hilus of the spleen, forming with the
greater sac, behind, a double fold, the lienorenal ligament (lien, lienis, spleen) in which run the splenic and pancreatic vessels. Anteriorly it forms with the greater sac another double fold, the lienogastric ligament or gastro-splenic omentum, in which pass the vasa brevia to the fundus of the stomach. This layer then covers the posterior surface of the stomach and makes the posterior layer of the lesser omentum, surrounding the three vessels and forming the anterior boundary of the foramen of Winslow. Now it forms a part of the greater sac and makes the anterior layer of the lesser omentum, covers the stomach anteriorly, dips down between it and the spleen to the anterior lip of the hilus to meet the lesser sac, and so forms the gastro-splenic omentum. It then covers the whole phrenic surface of the spleen, approaching the hilus from all sides, and meeting the lesser sac again from behind. Completing the lienorenal ligament, it turns back on the left kidney to the abdominal wall and courses as parietal peritoneum to the middle line again.

If we trace a section through the level of the foramen of Winslow, the pancreas and liver are introduced (Fig. 610).

Here again the peritoneum is traced from the mid-line anteriorly where it invests the round ligament of the liver, then it covers the right abdominal wall and posteriorly touches the diaphragm, passes anterior to the right kidney and crosses the inferior vena cava, where it makes the posterior boundary of the foramen of Winslow. It then extends to the left as the posterior wall of the lesser sac, in front of the aorta, splenic vessels, pancreas and left kidney to the hilus of the spleen. Now the pancreas is interposed between this layer and the left kidney, and the splenic vessels pass behind or just above the pancreas in the lienorenal ligament as before. The lesser sac makes a small blind pouch near the hilus of the spleen, and its peritoneum covers the posterior wall of the stomach, makes the posterior layer of the lesser omentum, bounds the foramen of Winslow anteriorly, and is then traced as in the last figure.

The peritoneum simply surrounds this section of the liver, not showing any coronary ligament. The peritoneal relations between stomach, kidney, pancreas, and spleen are shown in more detail in Fig. 611.

![Fig. 611.—Horizontal section through the stomach, pancreas, spleen, and the left kidney to show peritoneal reflections at hilus of spleen. Schematic. (G. S. H.)](image)

Here we see three pouches of peritoneum centering at the hilus of the spleen. Anteriorly and posteriorly are two from the greater sac and in the centre is the left blind extremity of the lesser sac. Should the structures at the hilus be grasped, the hand would enclose anteriorly a layer of the greater sac, then two of the lesser sac, then one of the greater, or four in all, and a section through them would show their cut edges standing out as two concentric rings (Fig. 612).
The layer of peritoneum covering the pancreas and attached to the spleen may be called the lieno-pancreatic ligament; it is really the anterior layer of the lieno-renal ligament.

![Diagram of the inner surface of the spleen, showing "peritoneal lines" at the hilus.](image)

**Fig. 612.—Inner surface of spleen, showing "peritoneal lines" at hilus. (From model of His.)**

We are now prepared to follow a whole layer of peritoneum instead of tracing it in certain lines.

**Parietal Peritoneum.**

The wall-implanted peritoneum follows essentially the wall of the abdomen and that of the pelvis, being bound firmly to the latter and quite loosely to the former. In most places it possesses a greater thickness than the visceral layer and a marked resistance. A separate piece will resist a pull of about fifty pounds. In the greater part of its extent it is intimately connected with the endo-abdominal fascia (transversalis and iliac fascia) which covers it as does the endo-thoracic fascia cover the pleura; or as the fibrous pericardium covers the serous pericardium.

**Anterior Wall of the Peritoneal Sac.**

From the umbilicus down along the inner surface of the anterior abdominal wall the parietal layer descends to the top of the bladder and Poupart's ligaments, and extends from here into the pelvis. In its course it is thin on the linea alba and umbilicus, and is fused with the parts beneath. On both sides of the linea alba, especially below in the pubic region, and close above Poupart's ligaments, the peritoneum is thicker and does not lie so close to the abdominal wall, as a well-developed properitoneal fatty layer comes between and separates them. Higher up along the linea alba the peritoneum is rather loosely attached and very often covers numerous, knobby, overlapped processes of fat which project inward, pliæ adipose.

Lower down the processes of the fatty layer project in the opposite direction toward the linea alba, and may push out through aponeurotic holes and make a fat hernia of variable size.

Above the umbilicus the peritoneum forms itself into a sheath which contains the beginning of the round ligament of the liver. It forms a pocket open from above which is in a position to receive a loop of intestine and to share in the formation of an umbilical hernia.
Below the umbilicus we have already noted the five longitudinal folds and the inguinal fossæ (p. 963).

The parietal layer passes from the anterior wall to the under surface of the diaphragm and clothes it up to the central tendon where the oesophagus and vena cava inferior pass through. From here it spreads out on one side to the liver, on the other to the stomach and spleen, and so changes into the visceral layer.

The parietal peritoneum of the posterior abdominal wall rests on small and limited spaces and passes over such structures as the kidneys, transverse duodenum, right and left colons, great vessel trunks, many lymph-glands and vessels and nerve-plexuses.

By means of a loose fatty connective tissue called retroperitoneal cellular tissue these structures fasten themselves together and themselves to the peritoneum. On this posterior wall to the left of the duodenum there may be as many as three infoldings or retroperitoneal pouches which will be described later.

**Upper Wall of the Peritoneal Sac.**

The lower surface of the diaphragm representing the roof of the abdomen is not covered wholly by peritoneum. Behind the central tendon it is partly free where the surface of the liver rests upon it and where the suprarenal capsules and kidneys come in contact with it. The greater part of the diaphragmatic covering is directly continuous with the anterior and lateral parietal layers, and is distinguished by its extreme delicacy and firm connection with the endo-abdominal fascia. In the cleft-like holes left between the costal and sternal parts of the diaphragm and between the costal and vertebral parts, peritoneum and pleura meet; these are called "weak places," and here a diaphragmatic hernia can be acquired.

A small surface of the diaphragm situated behind the lobus Spigelii gets a covering from the upper end of the posterior wall of the lesser sac which does not enter into continuity with the serous covering of either side, but on the left it turns into the mesial layer of the gastro-splenic omentum and on the right into the mesial layer of the hepatico-renal ligament.

**Inferior Wall of the Peritoneal Sac.**

This belongs in part to the false pelvis and in part to the true pelvis. In the former it is connected with the fascia iliaca. In the iliac fossa the peritoneum extends itself underneath and behind the rectum so that that structure hangs free in the peritoneal cavity. There is usually no mesorectum in the adult. Near the rectum there are **peri-rectal fossæ**, for later description. On the left side the peritoneum passes from within and without over the iliacus muscle and fascia to the formation of a very movable fold which surrounds the sigmoid flexure, the **meso-sigmoidae** or sigmoid mesocolon. Where this attaches to the intestine, opposite the brim of the true pelvis, the peritoneum raises itself into a fold which has been called **lig. mesenterico-mesocolicum** (W. Gruber), which on one side runs into the mesentery proper and on the other into the mesocolon of this flexure. It seems to have the purpose of limiting the deep descent of the rectal limb of the sigmoid flexure.

In the left leaf of the **meso-sigmoidae** is usually to be found the fossa **subsigmoidae** or intersigmoidae.

In the hollow of the true pelvis the peritoneum clothes that region of the lateral wall which in man extends between rectum and bladder, in woman between rectum and vagina, also between rectum and uterus. In the first it forms a pouch open above, **excavatio recto-vesicalis** or recto-vesical pouch. The mouth of the pouch is bounded by a crescentic fold of peritoneum on each side, the **pleca semilunaris**. The left one is usually the larger. They form the posterior false ligaments of the bladder. The depth of this pouch extends to within one inch of the prostate or within about 8 cm. of the anal orifice.
In the female we have seen that two pouches exist at the lower end of the peritoneal sac; a shallow one between bladder and uterus, \textit{excavatio vesico-uterina}; a posterior deep one between rectum behind and uterus and cervix and upper end of vagina in front. The deepest part is bounded on each side by a sharp semilunar fold as in the male, which folds are called \textit{sacro-uterine} ligaments, or, according to some, \textit{recto-uterine}. They pass from the upper part of the cervix in front and extend backward to the sides of the rectum toward the sacrum. This pouch has anteriorly the supravaginal cervix uteri and the upper fifth of the posterior wall of the vagina, and posteriorly the rectum and sacrum; it is the recto-vaginal pouch or the proper \textit{cul-de-sac} of Douglas. The space above this, between rectum and uterus, is called the \textit{recto-uterine pouch}.

On either side of the uterus the peritoneum forms a broad double layer passing to the side of the pelvis. It is called the \textit{broad} ligament, and each contains three important structures, anteriorly the round ligament of the uterus, in the middle and highest up the Fallopian tube, and posteriorly the ovary.

In a distended condition of the pelvic organs the pouches are filled by them, otherwise coils of small intestines and usually a part of the sigmoid flexure fall into the pelvic cavity.

**The Visceral Peritoneum.**

By this term one understands in general the prolongations of the peritoneum into its own cavity, usually from behind, covering or nearly surrounding a viscus. It is also applied to prolongations from parietal layers and those which pass bridge-like from one organ to another.

In the middle line, the peritoneum accompanies in its course from the umbilicus to the diaphragm the extraperitoneal obliterated umbilical vein, forms a fold around it which on one hand follows the vein (lig. teres) to the under surface of the liver, and on the other continues itself to the upper surface of the liver, and from there passes to the diaphragm as the \textit{lig. suspensorium hepatis}. It covers the concave surface of the diaphragm as far as the spot where the liver comes into direct contact with it and then passes upon the liver in a frontal direction as the anterior (or upper) layer of the \textit{lig. coronarium hepatis} (coronary and lateral ligaments). The left leaf of the suspensory ligament passes out over the upper surface of the left lobe of the liver, meeting above the left part of the coronary ligament, and the right leaf passes over the upper surface of the right lobe in the same manner. After clothing the convex surface of the liver it advances over the anterior acute margin and then covers the quadrate lobe to the portal fissure, the gall-bladder except where adherent to the liver, and under surfaces of the right and left lobes, to turn finally back to the diaphragm, forming the lower layer of the coronary and lateral ligaments. There is but one place, the portal fissure, where this layer does not turn back. Here by the out- and ingoing vessels it is obliged to descend to the stomach.

Farther to the left the peritoneum goes from the diaphragm to the stomach (cardia) as the \textit{lig. phrenico-gastricum} covering the anterior and left surfaces of the oesophagus; it descends from the diaphragm to the spleen as the \textit{lig. phrenico-lienale} or suspensory ligament; and to the splenic flexure of the colon as the \textit{lig. phrenico-colicum}.

From the fundus of the stomach, the peritoneum passes in a duplicature to the spleen as the \textit{lig. gastro-lienale} (gastro-splenic omentum), which covers the gastric surface of the spleen and is continued over its phrenic and renal surfaces as we have seen.

This omentum descends over the splenic flexure of the colon and there may be called \textit{omentum colicum}; thence it is connected with the posterior abdominal wall and descending colon.

The peritoneum leaves about one-third of the posterior surface of the left colon uncovered, forming no mesocolon usually; below, it surrounds the sigmoid flexure, forming a long mesocolon, which follows it into the pelvis.
Turning to the right side and above, we have seen the right part of the coronary and lateral ligament descending in two layers from the diaphragm.

Below the liver, the peritoneum passes to the stomach and duodenum as the *lig. hepato-gastricum* and *lig. hepato-duodenale*, both of which make the lesser omentum of two layers. A part of the right edge of this omentum passes to the hepatic flexure of the colon, called *lig. hepato-colicum*. The peritoneum from the neck of the gall-bladder to the duodenum is the *lig. cystico-duodenale*. Behind the foramen of Winslow and beneath the neck of the gall-bladder another thin layer passes to the right kidney, *lig. hepato-renale* (Fig. 615). Farther down the peritoneum from the posterior abdominal wall, continuous with the hepato-colic ligament, covers about two-thirds of the ascending colon as on the left side, making no mesocolon, and covers the whole of the cecum, making no meso-cecum, because the layers have fused into a close-fitting pocket with no attachments except above. This, as the mesentery proper, forms a little mesentery for the appendix (mesenteriolium) and descends into the pelvis.

**Mesentery.**—When the peritoneum on the vertebral column reaches the ante-
rior surface of the superior mesenteric vessels, it follows them down to the loops of small intestine surrounding all the jejunum and ileum, but not the duodenum; it returns to the spinal column, constituting the mesentery. It has a right upper and a left lower layer, between which are the mesenteric arteries and veins, lacteals, lymphatics, and nerves, all fused together by fatty connective tissue. The point of origin of the two layers is called "root of the mesentery" (Radix mesenterii) (Fig. 613).

It runs obliquely from the left side of the body of the second lumbar vertebra across the vertebral column, aorta, vena cava inferior, and third part of the duo-

---

![Diagram](image-url)
kind on the right side would press upon the right inguinal region; if upon the left side, would have an inclination to gravitate to the true pelvic cavity. At the root, the right layer is continued into the lower layer of the transverse mesocolon; on both sides the layers continue themselves, one into the inner lamella of the left colon and the other into that one of the right colon. The left layer continues downward into the peritoneum, covering the lumbar vertebrae, which passes over the promontory to the pelvic organs.

The Omenta and Bursa Omentalis.

The great omentum we have seen consists of four layers formed by an anterior descending lamella of two and a posterior ascending lamella of two. It was derived from the mesogastrium (Fig. 599). Its two middle layers (Fig. 606) constitute the walls of the lesser sac and come from the right leaf of the mesogastrium; its two superficial layers belong to the greater peritoneal cavity and come from the left leaf of the mesogastrium. Only in fetal life could the first and second or third and fourth layers be separated and only up to about the age of two years does the cavity exist between the second and third layers. Before that age and sometimes in adults the cavity of the great omentum can be distended by air introduced through the foramen of Winslow or a finger could be inserted into it through an incision made just below the stomach dividing the two anterior layers. This finger would come in contact with another introduced from right to left through the foramen of Winslow. This can rarely be done in the adult without breaking down adhesions, for the reason that at about the age mentioned the anterior lamella of two layers fell back upon the transverse colon and became adherent to the posterior lamella, obliterating the cavity of the great omentum, which may now be called the omental plate. Figure 606 shows the opportunity. This arrangement gives the stomach a direct connection with the transverse colon and the two layers descending from the greater curvature cannot be lifted from it. Our former great omentum may now be called gastro-colic omentum; some speak of the layers between stomach and colon only as the gastro-colic part of the great omentum.

This part connects on the left with the gastro-splenic omentum and on the right with the hepatic flexure of the colon and descending colon, meeting there the hepato-colic ligament, and is distinguished at those points as omentum colicum (Haller). In later time, the great omentum is a four-cornered curtain which hangs down from the great curvature of the stomach in front of the small intestines fused with the transverse colon, ending usually in a free edge and descending a little lower on the left side as evidenced by its greater frequency in left hernia. It may be tucked between the intestines or wholly pushed upward. It may accumulate much fat.

Its vessels—vasa epiploica—are chiefly derived from the art. gastro-epiploica sinistra, only the smallest part from the dextra. It is poorly supplied with lymphatics. Its nerves are from the celiac plexus.

The gastro-splenic omentum we have seen (Figs. 610 and 611) as a double fold, dipping in between the fundus of the stomach and the gastric surface of the spleen. It is where the greater sac has opportunity to touch the lesser sac between these two organs. In this fold, made by two sacs, the splenic artery sends its vasa brevia to the stomach.

The lesser omentum (omentum minus) or gastro-hepatic omentum or lig. hepato-gastricum passes nearly vertically between the transverse fissure of the liver and the lesser curvature of the stomach, continuous to the right upon the first part of the duodenum. This right free edge going to the duodenum, containing vessels, is called the lig. hepato-duodenale. The lesser omentum and hepato-duodenal ligament are made of two layers, one from the greater and one from the lesser sac. An index finger passed into the foramen of Winslow, if approximated to the thumb placed upon the anterior surface, includes the two layers, thin as they are. The
anterior layer at the right free border turns behind the vessels, now belongs to the lesser sac, and makes the posterior layer of the hepato-duodenal ligament and of the lesser omentum. These two layers below enclose the stomach, and to the left side form the gastro-splenic omentum. Above, the anterior layer is attached in front of the transverse fissure and then spreads over all the inferior surface of the liver. The posterior layer above is attached just behind the transverse fissure, and here separates from the anterior to pass backward and upward over the Spigelian lobule only. The combined layers leave the left end of the transverse fissure and run along the edges of the fissure for the ductus venosus, passing to the diaphragm and on that forward to the oesophagus, which the two layers partly surround, the anterior one covering its anterior and left side, the posterior one its posterior and right side, in part. The anterior one is the phrenico-gastric ligament. Between the two layers of the hepato-duodenal ligament at the right edge of the lesser omentum, the outgoing and ingoing vessels are arranged as represented in Fig. 615.

Near the duodenum there are three vessels, the common bile-duct to the right, the hepatic artery to the left, and behind and between the two the portal vein. At the transverse fissure of the liver the artery and vein divide into right and left branches for the right and left lobes, and the common bile-duct receives the cystic duct and the hepatic ducts descending from the two lobes. Besides these are lymph-glands and vessels and nerves, all surrounded by connective tissue which is called Glisson's capsule.

The foramen of Winslow (J. B. Winslow, 1743) or orificium epiploicum, is the point of communication between the bursa omentalis (lesser sac) and the greater sac. It may be round in shape, triangular or semilunar. It should admit about two fingers. It is best shown when the liver is tilted upward and to the right, and the intestines, with the first part of the duodenum, downward and to the left. Its boundaries are—above, the caudate lobe of the liver; below, the first part of the duodenum and the first part of the hepatic artery as it passes forward; in front are the right free border of the lesser omentum, lig. hepato-duodenale, with its contained vessels, hepatic artery, vena portae and common bile-duct; behind are the lig. hepato-renale and vena cava inferior.
As a result of closure of this foramen due to adhesive inflammation, a *hydrops sacculus* can be formed by a collection of serum in the lesser sac, and the stomach will rest on a sort of water-bed.

Another rare anomaly is a hernia through this foramen. A great part of the small intestines have worked their way through it by peristalsis into the lesser sac.

**The Lesser Sac or Bursa Omentalis.**—Between the mesogastrium and posterior wall of the stomach there was originally a three-cornered space with its apex turned to the left and base to the right (Figs. 599 and 600). During development the base has been narrowed to the foramen of Winslow. The cavity is called the lesser sac or omental bursa. Figure 606 shows that it sends a diverticulum up behind the Spigelian lobe of the liver, another downward known as the cavity of the great omentum, and in figure 610 we see the main chamber behind the stomach sending off a third pouch to the spleen and left kidney.

When the finger enters the foramen of Winslow it is able to mark out a circumscribed region confined by the Spigelian lobe anteriorly and the diaphragm behind. Push the finger to the left until it is obstructed and let it descend; at a level below the papillary tubercle of the liver it will slip under a prominent band, and can now ascend under the fundus of the stomach up to the posterior surface of the oesophagus; we can then push over to the spleen, or, if the subject be young enough, down into the great omentum.

The lesser sac seems to be subdivided. Huschke called the first portion, which receives the Spigelian lobe, the *bursa omenti minoris*, because it is just behind the lesser omentum.

The second large division going upward behind the stomach and downward into the omentum and over to the spleen was the *bursa omenti majoris*. Each communicates with the other by the *foramen omenti majoris*. These subdivisions are still found, and the constricting band is still present, caused by the gastric
artery, throwing forward a fold of peritoneum in relief. This is called the lig. gastro-pancreaticum (Fig. 616).

The figure shows the posterior wall of the bursa lying in front of the pancreas. Through the opening to the right and above may be seen the papillary tubercle of the Spigelian lobe.

The connection of the two bursae is narrowed by the tuber omentale of the pancreas and the gastro-pancreatic ligament which runs obliquely from the cardia to the anterior surface of the pancreas in about the middle line.

It is now proposed to call the first bursa the atrium bursae omentalis or antechamber, and the second bursa the bursa omental is proper.

The part behind the stomach persists throughout life. The surfaces are in immediate contact, and by their smoothness and moisture permit easy movements of the stomach in its various degrees of distention.

Recessus Peritonei or Retro-peritoneal Fossae.

In four or five different parts of the abdominal cavity there are regions of surgical interest from the possibility of the occurrence of retro-peritoneal herniae. One we have already noted, the foramen of Winslow, another is a phrenico-hepatic fossa at the left lobe of the liver. As many as three may occur at the upper end of the root of the mesentery: a duodeno-jejunal and duodenal fossae; an intersigmoid fossa to the outer side of the sigmoid flexure, a fossa ilico-subfascialis connected with a left Psoas minor muscle. Finally three fossae may exist in the neighborhood of the cæcum.

Henle says of the first one, "It is remarkable that a hitherto overlooked pocket has been brought to light by Von Brunn, 1874. It is on the under surface of the diaphragm, of various dimensions, and can be found in about one-half of the adults. It opens to the right from the left margin of the liver and extends to the left, parallel to the coronary ligament, sometimes only deep enough for the introduction of the point of a probe and sometimes distensible to a length of 13 to 16 cm. and to a diameter of 3 to 4 cm. Its existence depends on the atrophy of the left lobe of the liver. When the gland substance retracts, a flat peritoneal fold remains on the under surface of the diaphragm, penetrated by vessels and vasa aberrantia of the liver and often lodging separate particles of gland tissue. The pocket fossa phrenico-hepatis originates therefore when the anterior or posterior edge of the atrophied lobe, by far most frequently the anterior, fuses with the diaphragm. It develops after birth. In new-born and children it is not to be found."

Duodenal Fossae.

Jonnesco has found a series of three fossae in the vicinity of the ascending duodenum and duodeno-jejunal angle. They have all generally been called the duodeno-jejunal fossa, or fossa of Treitz.

1. The inferior duodenal fossa (Fig. 617) is most frequent, and occurs in about 75 per cent. of cases. It is situated to the left of the upper part of the ascending duodenum and has the shape of a cornucopia bound to the intestine. The apex of the fossa is directed to the right and almost touches the root of the mesentery.

Its widened mouth is turned upward and circumscribed by the free edge of the inferior duodenal fold. This fold is triangular, has a falloform edge with its concavity turned upward; its right margin rests on the anterior surface of the duodenum and its left on the prerenal peritoneum and is continuous with the parietal peritoneum. It contains no vessels, nor fat, and the duodenum is readily seen through it. The boundaries of the fossa are—this fold to the front and left, the ascending duodenum to the right, and the left side of the third lumbar vertebra behind. Its tip may extend to the anterior surface of the fourth lumbar vertebra. The depth may attain 3 cm.; its orifice admits the tip of the index finger.
Sometimes the fold is bound to the intestine and the fossa is then apparently lacking.

The vascular relations of this fossa are not close. The inferior mesenteric vein is about one finger's breadth to the left and the art. colica sinistra is as far below. The vessels have no causal relations and the fossa is non-vascular. Jonnesco met one case where the artery and vein were related to the fold.

The fossa described by Treitz and known as the duodeno-jejunal fossa of Treitz is this one, but it is "vascular," in which the inferior mesenteric vein runs in the edge of the crescentic fold and the inferior extremity of the fossa is formed by the colica sinistra artery. Treitz regarded the formation of the fossa due to the presence of the vessels (Fig. 618).

"The orifice of the fossa was limited on the right by the duodenum, on the left by the free edge of the duodenal fold. The fossa lay on the third lumbar vertebra left side, and in the bottom of a depression of the posterior abdominal wall limited by the pancreas, left kidney and aorta."

2. The superior duodenal fossa is present in about 50 per cent. It often coexists with the inferior one (Fig. 617). It is always at the level of the superior extremity of the ascending duodenum, and its orifice looks downward, opposed to the preceding. The orifice is limited by the edge of the superior duodenal fold, which presents the free semilunar base turned below. The summit of the fold is lost above in the inferior layer of the transverse mesocolon, its left side passes over into prerenal peritoneum, and its right side on to the duodenum and left leaf of mesentery.

The fossa is limited in front by this fold, to the right by the duodenum and is stopped above by the body of the pancreas and rests on the second lumbar vertebra in the angle formed by the left renal vein crossing the aorta. Its greatest depth is 2 cm. This fossa is always vascular, i.e. is related to the inferior mesenteric vein which passes to its left along its adherent parietal border and disappears under the pancreas; sometimes it enters the free fold covering the orifice.

3. The duodeno-jejunal or mesocolic fossa. This is found in 16 per cent.; it does not coexist with any other. Its existence necessitates that the duodeno-
jejunal angle should penetrate the root of the transverse mesocolon. This occurs in two forms: (1) a single simple fossa (Fig. 619), and (2) a double fossa. Below the duodenum is the inferior mesenteric artery, giving off the colica sinistra; passing over the fossa is the inferior mesenteric vein. This was originally described by Huschke in 1844. In drawing the jejunum forward and to the right, the mesocolon being raised, the duodeno-mesocolic ligaments are seen stretched between the duodeno-jejunal angle and mesocolon. They seem to be layers of mesentery passing into the mesocolon. Limited by these folds and by the upper surface of the duodeno-jejunal angle and the inferior mesenteric vein there appears an almost circular opening leading into a deep fossa. This plunges into the mesocolon and occupies a retro-peritoneal space to the left of the second lumbar vertebra, limited above by the pancreas, on the right by the aorta, and on the left by the left kidney. In this cavity is the angle of the duodeno-jejunal flexure and higher up can be seen under it the left renal vein. The orifice admits the little finger and its depth is 2 or 3 cm.

The inferior mesenteric vein passes at first along the adherent mesocolic border of the left fold and then its concavity crosses near the orifice.

Jonnesco has seen one case of a double duodeno-jejunal fossa where there were three ligaments. All these are related to the inferior mesenteric vein.

It is not believed that any of these are pathological. They are more or less developed in children and new-born.

**Classification.**

I. Duodenal fossae (may co-exist).

- **Inferior**
  - Non-vascular most often. If vascular, is the fossa of Treitz.

- **Superior**
  - Always vascular, simple venous.

II. Duodeno-jejunal or mesocolic fossa (never coexists with the preceding).

- **Simple**
  - Always vascular, venous.

- **Double**

**Fossa Intersigmoidea.**

Under the name *intersigmoid* or *subsigmoid fossa*, Treitz described a funnel-shaped recess of the peritoneum, commonly found in the fetus, next most often in the child, and rather rarely in the adult. Its mouth opens below in the left iliac fossa on the left side of the root of the mesentery of the sigmoid flexure. To find it, turn the flexure over to the right (Fig. 620).

The opening usually lies upon the left external iliac vessels at the interval between the edges of the Iliacus and Psoas muscles.

The pouch runs up under the parietal peritoneum of the posterior abdominal wall and ends blind at the point of division of the inferior mesenteric artery into the colica sinistra and its descending branch. More often the fossa is incompletely subdivided by a falciform projection of the wall. Sometimes two separate fossae extend from a single opening. Probably the fossa is formed by the separation of the two layers of the peritoneum behind the descending colon which
formerly made the descending mesocolon. On the right side the subcaecal fossa is made in a similar way.

"The Psoas minor muscle can raise the peritoneum into a fold by the spreading out of its tendon of insertion into the fascia iliaca; at the side of this a peritoneal fossa may exist which in some cases receives a part of the descending colon." Biesiadecki, who described it, gave it the name fossa iliaco-subfascialis. This fossa, of course, is of slight importance.

**Pericaecal Fossae.**

At least three fossae are to be found in the caecal region. There is no agreement upon their frequency and nomenclature. Just above the ileo-colic junction between the end of the ileum and ascending colon, bounded in front by an ileo-colic fold may be the ileo-colic fossa, also called superior ileo-caecal. (Luschka.) It is just where the mesentery changes into the peritoneal coat of the ascending colon. It is smaller and less constant than the next.

Underneath the ileum, between it and the caecum, is the ileo-caecal fossa, which may be called the inferior ileo-caecal, and has been described as the subcaecal. It lies between two definite folds of peritoneum, the formation of which requires explanation. Originally in the human foetus there were three folds passing between the contiguous surfaces of the ileum and caecum. These are normal in the spider monkey (Fig. 621).

They are called anterior vascular, posterior vascular, and intermediate non-vascular folds. In the human subject the anterior vascular and the middle non-vascular folds unite on the caecum, but do not descend upon the appendix; the posterior vascular fold with its contained posterior ileo-caecal artery passes to the appendix and forms its mesentery. The space left between this fold behind and the middle non-vascular fold in front is the ileo-caecal fossa (Fig. 622).

The subcaecal fossa is directly behind the caecum; it is really post-caecal. Its fundus may pass up behind the ascending colon, i.e. the caecum in descending
from its subhepatic position has never contracted extensive adhesions to the posterior abdominal wall, and a fossa is left between the layers of its mesocolon.

The ascending colon can be easily separated from its posterior connections. These fossæ may nearly all be the site of retro-peritoneal herniae. Attention was first called to such herniae as early as 1778, and a most important work on the subject appeared in 1857 by Treitz, who described the fossa of his name and reported cases of "retro-peritoneal" herniae through his fossa.
Such cases are sometimes seen in the dissecting-room, say about 3 in 1000 subjects.

**Contents of the Abdominal Cavity.**

They are intra-peritoneal and retro-peritoneal, two groups. The stomach, small and large intestine, liver, and spleen receive a more or less complete investment of peritoneum, and are called intra-peritoneal organs. The other group, to which belong the kidneys, suprarenal capsules, pancreas, and great vessels are only covered on the side turned toward the abdominal cavity by parietal peritoneum and are retro-peritoneal.

**THE STOMACH.**

**Form and Size** (Figs. 623 and 624).—The stomach is a sac-like, pear-shaped dilatation of the alimentary canal placed between the oesophagus and beginning of the small intestine. Its big end is directed above and to the left, to the diaphragm, its small end below and to the right. The beginning of the stomach or its mouth is the *cardia* or *cardiac opening*, which passes from the oesophagus like
an inverted funnel without visible external limit. On the inner surface a definite line is seen between the oesophagus and cardia. Above the line the mucous membrane is whitish and made largely of pavement epithelium, while below the color is red and the mucous membrane shows characteristic cylindrical epithelium. Sometimes an external ring as well as an internal projection is found between cardia and the rest of the stomach, forming a kind of \textit{antrum cardiaeum}.

Passing from the cardia to the left and above, we find the first great pouch, the blind sac or \textit{fundus}, whose relative size varies with age. In early youth it is slightly developed, in adult man it forms about one-fifth of the stomach.

This continues on the right into the body of the stomach, which has two surfaces—anterior and posterior—and two borders. The anterior surface looks upward and forward, the posterior backward and downward, and they are included between the borders \textit{lesser curvature}, concave and turned to the right and above, and \textit{larger curvature}, convex and three or four times as large as the lesser, turned to the left and below (Figs. 623 and 624).

At the right the body of the stomach gradually contracts toward its duodenal end. Then follows a second smaller part of the stomach, the \textit{portio pylorica}, which includes the \textit{antrum pyloricum}, whose form and size vary. Usually the antrum appears as a double pouch; the flatter one is higher and extends from the lesser curvature to the beginning of the duodenum. It is not very distinctly marked off from the body. The other lies laterally and is separated by a more or less deep notch from the greater curvature (Fig. 627).

Sometimes a third one is found under this last one. On the inner surface of the stomach there is sometimes a mucous fold, \textit{plica praepylorica}, separating the antrum from the body of the stomach. The pouches representing the antrum pylori are caused by two flat ligamentous bands some millimeters wide, one running along the anterior wall, one on the posterior. They are called \textit{pyloric ligaments} (lig. pyloricum) and lie between the muscular and serous coats and are closely fused with the latter (Fig. 627).

The division between the stomach and intestine is marked externally by a circular constriction, \textit{sulcus pyloricus}, and more deeply by a muscular ring, \textit{sphincter pyloricus}, and internally by a corresponding projection of mucous membrane called \textit{valvula pylorica} or \textit{pylorus} (Fig. 625).

The valve usually presents a round opening, bigger or smaller—\textit{orificeum duodenale}—which may have a central or eccentric position. It may not be an enclosing ring but a crescentic projection, and rarely consists of two halves lying opposite each other.

The first part of the duodenum is often pouchled, called \textit{antrum duodeni}.

The size of the stomach varies according to age, sex, individual, and degree of distention.

A woman's stomach increases more in length, is more slender, and in general smaller than that of a man. In moderate distention Sappey found the greatest diameter of the stomach to be 24–26 cm. (10–12 inches), from the lesser to the greater curvature 10–12 cm. (4–5 inches), and from the anterior to the posterior wall 8–9 cm. (3½ inches). The distance between the two orifices is three to six inches. Luschka, by blowing up the stomach, found its long axis to measure 34 cm., greatest vertical diameter 15 cm., greatest antero-posterior diameter 11.5 cm., and smallest antero-posterior diameter, at pylorus, 8.7 cm.

In the empty condition, as in the dead subject, the greatest diameter is reduced to 18–20 cm., the second diameter is 7–8 cm., and the third disappears as the two walls touch.
The weight of the freed stomach is in the male about four and a half ounces. Its normal capacity in the adult male is 2.5-4 litres (5-8 pints).

A blow-up stomach dried contained 5 pounds of water, female; and 8 pounds, male.

**Position and Relations of the Stomach.**

It lies in the epigastric region and left hypochondrium, rarely in the right hypochondrium, about five-sixths to the left of the median line, and one-sixth to the right. Of the left segment the greater part lies in the left hypochondrium, viz. the cardia, fundus, and the most curved part of the body; the rest of the body and a part of the pars pylorica fall in the left part of the epigastrium. The only part belonging to the right half includes a very small portion of the pars pylorica and the pylorus. The stomach then lies under the diaphragm and liver, above the jejunum, ileum, and transverse colon, extending its greater part into the left hypochondrium and smaller part into the epigastrium between the spleen on the left and gall-bladder on the right. It does not lie transversely nor yet so
vertically as Luschka puts it, unless in the infant or in the female deformed by corsets. It is directed from above and the left downward and forward to the right. An empty stomach may hang nearly vertically and present an anterior and a posterior surface, but there is usually some obliquity. If the small intestines are much distended it may be transverse, or if rigor mortis be rapid it may be cylindrical, especially below.

In moderate distention the cardia lies 2–3 cm. (1 inch) below the esophageal opening of the diaphragm (Fig. 626).

This point is distant about 11 cm. from the anterior body-wall, is opposite the sternal junction of the left seventh costal cartilage, and that corresponds to the left side of the eleventh thoracic vertebra. A horizontal line drawn backward from the ziphoid cartilage to the vertebral column marks the transition from cardia to esophagus. The fundus is 3–5 cm. higher than the cardia. It lies in the left hypochondrium and, if distended, against the left cupola of the diaphragm, which separates it from the overlying lung. Its highest point on the cadaver reaches a horizontal line connecting the sternal end of the left sixth costal cartilage and the vertebral end of the tenth rib.

In its full condition the fundus lies upon the upper half of the inner surface of the spleen, connected by the gastro-splenic omentum. A full stomach therefore may intrude upon respiration, or it may touch the left part of the central tendon and exert an influence on the heart’s action, or may compress the big vessel trunks on the vertebral column.

The anterior surface of the body of the stomach touches on the left the posterior surface of the anterior thoracic wall, where it is covered by the anterior parts of the seventh, eighth and ninth ribs. The part of the lesser curvature lying next is covered by the liver. Thus one finds in the so-called gastric fossa of the abdomen not only the stomach but the liver in front of it. Between the part covered by the liver and that covered by the left ribs, there is a triangular section of about 40 sq. cm. of the anterior wall of the stomach in contact with the abdominal wall. It is bounded on the left by the cartilaginous ends of the seventh, eighth and ninth ribs, on the right by the anterior margin of the liver, and below by the transverse colon. This is the only part of the stomach to be actually seen when the subject is opened. This is the part which the surgeon can readily approach in operation. In the new-born the stomach is wholly covered by the left lobe of the liver.

The posterior surface of the body covers, in moderate distention, the end of the transverse colon and its splenic flexure. The greater part of the posterior surface of the stomach rests on a “bed” formed largely by the transverse colon and its upper layer of mesocolon. If the organs are hardened in situ, the transverse mesocolon will be found to present a concavity directed upward, corresponding to the convex shape of the stomach, and thus the latter receives great support. Still in this bed are the pancreas with the splenic vessels running along its upper border, the upper part of the left kidney, the left suprarenal capsule, spleen, bursa omentalis, duodenum, and left crus of diaphragm (Fig. 680). Cases are known where ulcers on this surface of the stomach have perforated branches of the splenic artery and caused fatal hemorrhage.

The lesser curvature, with its concavity directed to the right and upward toward the under surface of the liver, descends in front of the vertebral portion of the diaphragm at first quite obliquely along the left side of the eleventh and twelfth thoracic vertebrae, then crosses the vertebral column at the level of the first lumbar vertebra, and then ascends into the pylorus. The greater curvature forms a convex arch directed below. In moderate distention it crosses the epigastrium in a line which connects the cartilages of the two ninth or tenth ribs. This line usually lies two fingers’ breadth above the umbilicus. In great distention the great curvature can reach it, and in pathological cases can descend far below it. The portio pylorica, bent backward and outward, lying in the epigastrium, is covered by the quadrate lobe of the liver. The pylorus is to the right and some-
what below the ziphoid process between the sternal and parasternal lines on a level with the upper edge of the first lumbar vertebra. This may extend into the right hypochondrium. In an empty, fasting stomach these relations are all changed and the surfaces of contact are small. In a well-filled stomach a twist of the organ occurs, so that the anterior surface comes to be more superior and the posterior surface more inferior. The lesser curvature is more directed toward the vertebral column and the greater curvature toward the anterior abdominal wall. The pylorus also moves more to the right.

**Relations of Stomach in Detail.**

**Cardia.**
Opposite left 7th chondro-sternal junction.

**Fundus** reaches left 6th costal cartilage and left cupola of diaphragm.

**Pylorus** reaches upper border of 1st L. vertebra to the right of the median line.

Lowest edge of greater curvature in median line reaches to within two fingers' breadth of the umbilicus.

**Anteriorly:**
- Diaphragm;
- Thoracic wall formed by anterior parts of 7th, 8th, and 9th ribs;
- Quadrato and left lobes of liver;
- Anterior abdominal wall.

**Posteriorly, or “bed:”**

- Diaphragm;
- Left crus of diaphragm;
- Aorta and vena cava inferior;
- 1st lumbar vertebra;
- Coeliac axis;
- Bursa omentalis (lesser sac);
- Splenic flexure of colon;
- Transverse colon;
- Transverse mesocolon (upper layer);
- Gastric surface of spleen;
- Left kidney and capsule;
- Pancreas;
- Splenic vessels;
- 4th part of duodenum.

**Right End:**
Junction of transverse colon and under surface of liver.

**Left End:**
- Spleen;
- Diaphragm.

The peritoneal relations of the stomach have in general been described. It presents double “peritoneal lines” on both curvatures and fundus, showing the cut edges of peritoneum. Above, in front of the cardia is the attachment of the gastro-phrenic ligament running down along the lesser curvature as the anterior layer of the lesser omentum. Behind it, separated by a linear space where the stomach is uncovered, is the line for the posterior layer of the lesser omentum. Larger triangular spaces are left uncovered at either end of the stomach. On the greater curvature is the double line indicating the two layers of the anterior lamella of the great omentum running on the left into the two lines of the gastro-splenic omentum.

**Points of Fixation of the Stomach.**—It is a part very well secured, especially by the oesophagus fastened to the diaphragm and by the duodenum firmly bound
to the vertebral column. Some peritoneal folds also aid, as the lig. phrenico-gastricum connecting the cardia to the diaphragm. To the right this joins the lesser omentum, which is very thin, but farther to the right is the strong lig. hepato-duodenale, which confines the pylorus. The great omentum and gastro-splenic afford no fixation to the stomach. The spleen has no firmness of position, so the stomach gains nothing by that attachment. The great omentum hangs free in front of the intestines, and could only modify the position of the stomach when caught in a hernia.

Alterations in Position.—There is no organ in the body the position and connections of which present such frequent alterations as the stomach. During inspiration it is displaced downward by the descent of the Diaphragm, and elevated by the pressure of the abdominal muscles during expiration. Its position in relation to the surrounding visceras is also changed according to the empty or distended state of the organ. When empty it lies at the back part of the abdomen, some distance from the surface. The left lobe of the liver covers it in front, and the under surface of the heart rests upon it above and in front, being separated from it by the left lobe of the liver, besides the Diaphragm and pericardium. This close relation between the stomach and the heart explains the fact that in gastralgia the pain is generally referred to the heart, and is often accompanied by palpitation and intermission of the pulse. When the stomach is distended the greater curvature is elevated and carried forward, so that the anterior surface is turned upward and the posterior surface downward, and the stomach brought well against the anterior wall of the abdomen. The Diaphragm at the same time is forced upward, contracting the cavity of the chest; hence the dyspncea complained of, from inspiration being impeded. The heart is also displaced upward; hence the oppression in this region and the palpitation experienced in extreme distention of the stomach. Pressure from without, as from tight lacing, pushes the stomach down toward the pelvis. In disease also the position and connections of the organ may be greatly changed, from the accumulation of fluid in the chest or abdomen or from alteration in size of any of the surrounding visceras.

Structure.—Its walls are composed of four coats named in order—serous, muscular, submucous or areolar, and mucous.

The serous coat, peritoneum, is thin, smooth, and moist, allowing some mobility of the organ. It encloses the stomach between two layers, derived from the lesser omentum. Where the layers come upon the surface and leave it again—greater and lesser curvature—they lie loosely and leave a small interspace, in which blood-vessels, nerves, lymph-vessels and glands, take their course. Elsewhere the serous layer is held so tightly by subserous tissue to the muscular coat that it can only be removed artificially in small bits. There is a small posterior area near the cardia not covered by peritoneum which touches the diaphragm.

Musculature.—Three sets of unstriated muscular tissue are here included—longitudinal, circular, and oblique. Their purpose is to set the stomach contents in motion, to push them on, and to empty glandular secretion.

The external or longitudinal layer is very incomplete and is directly continuous with the longitudinal fibres of the œsophagus (Fig. 627). There is a connected layer on the outer side of the cardia, from which fibres

---

1 This is denied by Dr. Lesshaft of St. Petersburg, who states that "if the stomach is enlarged, no one part can be alone displaced, but all parts are equally moved by the distention" (Lancet, March 11, 1852, p. 400).
stream outward in all directions with unequal lengths. They are thickest along the lesser curvature. At the fundus and anterior and posterior walls there are only a few delicate bundles which seem to pass deeply between the circular fibres. The substantial longitudinal layer is united at the pylorus, where it is firmly bound to the serous coat and wholly covers the circular layer. To this layer belong the ligamenta pylorica. This layer passes over the pylorus to the duodenal wall. The longitudinal layer stands in closest relation to the apertures of the stomach.

Circular fibres cover the whole length of the stomach in an uninterrupted layer, but they are not everywhere collected with the same thickness and strength (Fig. 628). They are fewest on the fundus, where there is a sort of whorl. They pass along the stomach in circles at right angles to its axis, and become thickest at the pylorus, where they form the sphincter pyloricus. On the margin of the duodenum they abruptly cease. Above they seem connected with the circular coat of the oesophagus. By this set the peristaltic movements of the stomach are produced, carrying the contents to the pyloric end, where is experienced a strong compression and after that a relaxation of the antrum pyloricum and of the pylorus, and then the longitudinal fibres can exercise their expulsive strength on the whole circumference.

The oblique fibres, like the longitudinal, form an imperfect layer. They lie under the circular layer, and are thought to be derived from it. They can best be seen when the stomach is turned inside out and the mucous membrane is removed. This group is said to have no counterpart in any region of the digestive tract. They are not believed to represent the ring fibres of the oesophagus. They form a loose layer to the left of the cardia and pass superiorly and posteriorly toward the greater curvature. The upper edge of these fibres forms a raised ligamentous strip on either side of the lesser curvature, about a finger’s breadth below it; this goes in a flat curve (seen on inner surface of stomach) from the left of the cardia on both sides toward the portio pylorica. At the apex of the fundus and toward the greater curvature the fibres grow smaller and paler. The bundles are apt to split into a sort of wicker-work, leaving longitudinal clefts. Delicate fibres run from these to the submucosa and to the circular fibres.

These fibres seem able to bring nearer together the cardia and pylorus, the greater and lesser curvatures, and also the contiguous surfaces of the anterior and posterior walls, resulting in the function of the pharyngeal groove in ruminants. A sort of half canal is formed along the lesser curvature, where fluid could be sent directly from oesophagus to pylorus or various juices could be sent in the opposite direction.

The submucous coat consists of loose, filamentous, areolar tissue, connecting the mucous and muscular layers, thus allowing free movement to the former. It supports the blood-vessels previous to their distribution to the mucous membrane. The rugae of the stomach involve the mucous and submucous coats.

The mucous membrane is thick, its surface smooth, soft, and velvety. In the fresh state it is of a pinkish tinge at the pyloric end, and of a red or reddish-

---

brown color over the rest of its surface. In infancy it is of a brighter hue, the vascular redness being more marked. It is thin at the cardiac extremity, but thicker toward the pylorus. During the contracted state of the organ it is thrown into numerous plaits or rugae, which for the most part have a longitudinal direction, and are most marked toward the lesser end of the stomach and along the greater curvature. These folds are entirely obliterated when the organ becomes distended.

**Structure of the Mucous Membrane.**—When examined with a lens the inner surface of the mucous membrane presents a peculiar honeycomb appearance, from being covered with small shallow depressions or alveoli of a polygonal or hexagonal form, which vary from $\frac{1}{100}$ to $\frac{2}{100}$ of an inch in diameter, and are separated by slightly elevated ridges. In the bottom of the alveoli are seen the orifices of minute tubes, the *gastric follicles*, which are situated perpendicularly side by side throughout the entire substance of the mucous membrane.

The gastric glands are of two kinds, which differ from each other in structure,
membrane of the stomach, the tubes with shorter and more cubical cells, which are finely granular. The peptic glands (Fig. 630) are found all over the surface of the stomach. Like the pyloric glands, they consist of a duct into which open two or more cecal tubes. The duct, however, in these glands is shorter than in the other variety, sometimes not amounting to more than one-sixth of the whole length of the gland; it is lined throughout by columnar epithelium. At the point where the terminal tubes open into the duct, and which is termed the neck, the epithelium alters, the cells becoming much shorter and opaque: the lumen also becomes suddenly constricted, and is continued down to the bottom of the tubes as a very fine channel. Here also are found, between the epithelium and the basement membrane, large spheroidal, coarsely granular cells, which were formerly termed peptic cells, and which produce an outward bulging of the basement membrane. They are seen throughout the remainder of the tube at intervals, and give it a beaded or varicose appearance. Below the neck the terminal tubes, in addition to these isolated spheroidal cells, are occupied with finely granular, angular cells (columnar, Klein), leaving only a small channel in the centre. They are continuous with the short columnar cells of the neck, and are termed the central or chief cells, because they are believed to be principally concerned in the secretion of the gastric juice. The peptic cells, which were formerly supposed to possess this office, are now termed parietal or oxyntic cells. Between the glands the mucous membrane consists of a connective tissue framework, with lymphoid tissue. In places this latter tissue, especially in early life, is collected into little masses, which to a certain extent resemble the solitary glands of the intestine, and are by some termed the lenticular glands of the stomach. They are not, however, so distinctly circumscribed as the solitary glands. The epithelium lining the mucous membrane of the stomach and its alveoli is of the columnar variety. Beneath the mucous membrane, and between it and the submucous coat, is a thin stratum, of involuntary muscular fibre (muscularis mucosae), which in some parts consists only of a single longitudinal layer; in others, of two layers, an inner, circular, and an outer, longitudinal.

Vessels and Nerves.—The arteries supplying the stomach are—the gastric, the pyloric and right gastro-epiploic branches of the hepatic, the left gastro-epiploic and vasa brevia from the splenic. They supply the muscular coat, ramify in the submucous coat, and are finally distributed to the mucous membrane. The arrangement of the vessels in the mucous membrane is somewhat peculiar. The arteries break up at the base of the gastric tubules into a plexus of fine capillaries which run upward between the tubules, anastomosing with each other, and ending in a plexus of larger capillaries, which surround the mouths of the tubes and also form hexagonal meshes around the alveoli. From these latter the veins arise, and pursue a straight course backward between the tubules, to the submucous tissue, and terminate either in the splenic and superior mesenteric veins or directly in the portal vein. The lymphatics are numerous; they consist of a superficial and deep set, which pass through the lymphatic glands found along the two curvatures of the organ. The nerves are the terminal branches of the right and left pneumogastric, the former being distributed upon the back, and the latter upon the front part of the organ. A great number of branches from the sympathetic also supply the organ.

Surgical Anatomy.—Operations on the stomach are frequently performed. By "gastrotomy" is meant an incision into the stomach for the removal of a foreign body, the opening being immediately afterward closed—in contradistinction to "gastrotomy," the making of a more or less permanent fistulous opening. Gastrotomy is probably best performed by an incision in the linea alba, especially if the foreign body is large: by a cut from the ensiform cartilage to the umbilicus, but may be performed by an incision over the body itself, where this can be felt, or by one of the incisions for gastrotomy, to be mentioned immediately. The peritoneal cavity is opened, and the point at which the stomach is to be incised decided upon. This portion is then brought out of the abdominal wound and sponges carefully packed around. The stomach is now opened by a transverse incision and the foreign body extracted. The wound in the stomach is then closed by Lembert’s sutures—i. e. by sutures passed through the peritoneal and muscular coats in such a way that the peritoneal surfaces
on each side of the wound are brought into apposition, and in this way the wound is closed. *Gastrostomy* is performed in two stages: The first stage consists in opening the peritoneal cavity and stitching the stomach to the abdominal wall. The second stage consists in opening the stomach after a few days have elapsed and adhesions formed between the peritoneal surfaces of the stomach and abdominal wall. The operation is usually performed by an oblique incision about one finger's breadth below and parallel with the margin of the left costal cartilages, commencing an inch and a half from the median line and being about three inches in length. Some surgeons prefer a straight incision, beginning opposite to the end of the eighth intercostal space, and passing down for three inches over the Rectus abdominis muscle. The skin, fasciae, and muscles are to be severally divided down to the peritoneum. Howe recommends that the sheath of the Rectus should be opened longitudinally, and the fibres of this muscle separated, and not cut, in the same direction, so as to secure a sphincter-like action around the opening. After the peritoneum has been opened the stomach is recognized by its pink-red color and smooth surface. It is to be pulled up into the wound and sutured to the opening. This may be done in several ways, but in whatever way it is done the following points should be carefully attended to: (1) To take up the stomach only to pass the needle through the serous and muscular coats, and avoid puncturing the mucous membrane. (2) To take up plenty of the muscular coat. (3) In passing the needle through the parietes of the abdomen to be careful to include the parietal peritoneum. (4) To enclose a circle of the stomach at least an inch in diameter. If the symptoms admit of it, the parts are now to be left quiet for four or five days, and a small puncture is then to be made through the exposed portion of the stomach, and a gum elastic catheter passed through it into the viscus, through which fluid can be injected in small quantities at first. In more urgent cases it may be necessary to make the opening much earlier.

Excision of the pylorus has occasionally been performed, but the results of this operation are by no means favorable, and in cases of cancer of the pylorus gastro-enterostomy is generally preferred. The object of this operation is to make a fistulous communication between the stomach, on the cardiac side of the disease, and the small intestine, as high up as is possible.

**THE INTESTINAL CANAL.**

This, in the form of a curved tube, passes uninterruptedly from the pylorus to the anus. It has a remarkable length of about six times the height of its possessor, though in the adult it may be independent of the age, height, or weight. In this relation man stands midway between the herbivores, *e. g.* rabbit with very long intestine, and carnivores, *e. g.* lion, whose intestine is three times the length of its body. There is some evidence to prove that vegetarians may have a longer intestine than those living on a mixed or a flesh diet. The wall of the intestine offers throughout a serous, muscular and mucous coat presenting many modifications, by which the upper four-fifths is distinguished as *small intestine* and the lower fifth as *large intestine*.

**The Small Intestine.**

By this term is understood the part of the alimentary canal extending from the pylorus to the ileo-cecal valve. Its average length is about 8 metres or (Luschka) 25 feet, or 6 metres longer than the whole body; Treves says 22½ feet, and Quain 22 feet. The extremes found are 34 feet and 8 feet. Its circumference decreases from the stomach toward the large intestine from 12.8 cm. to 9.5 cm. Its capacity, inflated and dried, is 15 pints. The wall of the ileum is so thin and translucent that a newspaper may be read through it. The small intestine is divided into three parts:

1. Duodenum (12-finger intestine);
2. Jejunum (empty intestine);
3. Ileum (curved or twisted intestine).

**The Duodenum.**

The *duodenum* begins at the sulcus pylorica and ends at the *duodeno-jejunal angle* or *flexure*, where it becomes jejunum. It was named by Herophilus, but it possesses neither the length nor the breadth of twelve fingers.

A better name would be *intestinalum pancratium* (Luschka) on account of its intimate relation to the pancreas. In the adult male its axial length is 30 cm. (or 10–12 inches), and its usual circumference 12 or 13 cm. (1.5 to 2 inches in diameter). Authors fail to agree on its direction and form.
1. French authors give three portions, ending it at the superior mesenteric vessels; superior horizontal, vertical, and inferior horizontal parts.
2. To this third part Henle, Kranse, Quain, and others add a fourth oblique part ascending from right to left.
3. Luschka, His, and Braune describe an annular form.
4. Cruvelhier, Young, and Treves describe a fourth portion 2 cm. long, coming forward at the end of duodenum, by joining the duodeno-jejunal junction. They are all described as different types, of which, according to Jonnesco, there are three.

1. Annular or circular type, infantile;
2. U-shaped type, adult, rare in infant
3. V-shaped type, (Fig. 632 and 633).

The typical annular form is always found in the child up to about the age of seven (Fig. 631).

The terminal point of this variety is strongly fixed to the left side of the first lumbar vertebra and is exactly on the same level as the beginning of the duodenum, and hence is behind the stomach (Fig. 634).

Between these points, the one fastened by the muscle of Treitz and the other by the hepato-duodenal ligament, the duodenum describes a regular curve in front of the vertebral column. This ring is filled and its margins overlapped by the head of the pancreas, the neck of which is limited by the two extremities of the ring.

In the adult this type may be found, but the terminal point does not usually attain the same level that the origin has; it is pushed back more to the left as though the developing neck of the pancreas had forced the duodenal ring to open more widely for its lodgment.

**Course of the Adult Duodenum.**—Separated from the pylorus at the right of the upper edge of the first lumbar vertebra there is usually at first a bottle-shaped dilatation, the *antrum duodeni*. The direction of the first portion depends on the condition and length of the stomach and position of the pylorus. With an empty stomach the first part is nearly horizontal and transverse. With a distended stomach, it is nearly antero-posterior; its distal end is stationary and its proxim...
mal end is not. In general, it is directed upward to the right and backward under the quadrate lobe of the liver and curves backward under the neck of the gall-bladder to make a sharp turn to the right surface of the lumbar column. This is the initial curve. It is so closely related to the liver and gall-bladder that it is stained by bile soon after death. Behind it are the common bile-duct, vena portae, and gastro-duodenal artery. Behind and to the left is the neck of the pancreas, and below, the head of the pancreas. Its anterior surface and a part of its posterior surface near the pylorus are wholly covered by peritoneum, derived from the lig. hepato-duodenale. The length of this portion is so variable, "two inches" (Quain), "often almost inappreciable" (Jonnesco), that the latter author unites it and the curve which follows it under one name, the superior hepatic curve of the duodenum (Fig. 634). Placed on the vena cava inferior and

right kidney, it next descends along the right side of the vertebral column a variable length, usually to the body of the fourth lumbar vertebra, starting from the right side of the first. This is called the vertical, descending, or second portion. It is three or four inches long and divided into two parts, supracolic and infracolic, since the transverse colon crosses its middle third. The two layers of transverse mesocolon (Fig. 679) leave an interspace uncovered by peritoneum where the approximated surfaces of duodenum and transverse colon touch except for a little areolar tissue. Above and below this place its anterior surface and

![Fig. 634.—View of duodenum and its five parts, a, b, c, d, and e, and pancreas. The part of stomach removed is indicated by dotted lines. (Testut.)](image-url)
sides are covered with peritoneum. Above it is in contact with the right lobe of the liver, leaving its "impression." Posteriorly there is no peritoneum, areolar tissue connecting it with the kidney, vessels at its hilus, and vena cava. The pancreatic and common bile-ducts open into its postero-internal wall below the middle. The head of the pancreas is to its inner side.

Now the duodenum changes its direction and passes more or less horizontally from right to left in front of the great vessel-trunks and crura of the diaphragm, moulding itself over the third or fourth lumbar vertebra. This is the transverse or pre-aortic portion and is two or three inches long. The head of the pancreas is above it. It is crossed by the superior mesenteric vessels and mesentery. Its anterior surface is covered by the peritoneum of the mesentery, but is separated from it when the superior mesenteric vessels cross it from above. On the right its posterior surface has no peritoneal covering, but on the left the posterior layer of the mesentery may be prolonged behind it. In the middle line this part of the duodenum is situated at the point of divergence of the two layers of the root of the mesentery (Fig. 606).

Thence the duodenum ascends along the left side of the vertebral column and aorta, touches the left kidney, lies upon the left crus of the diaphragm, and ends at the left side of the second or first lumbar vertebra. This part is about two inches long and is called the fourth or ascending portion.

It often turns abruptly forward to unite with the jejunum and form the duodeno-jejunal angle. This terminal portion, about 2 cm. long (less than one inch), has been described as the fourth portion, but with the U-shaped duodenum it makes the fifth portion.

The duodenum begins with a short portion looking backward and ends with a short portion looking forward.

The five parts are—1. Superior hepatic curve, or pars superior horizontalis. 2. Descending or vertical portion. 3. Pre-aortic or transverse portion. 4. Ascending portion. 5. Terminal portion to form (6) the duodeno-jejunal angle.

When the above arrangement is complete, the duodenum has the form of the letter U, considering the second, third, and fourth portions (Figs. 632 and 634). When, however, the descending and ascending portions unite by a short curve or angle, the transverse portion is practically lacking, and the duodenum is then V-shaped (Fig. 633). The angle of the V is thrown to the right against the vena cava, and the ascending portion crosses the abdominal aorta at a sharp angle. The U-shaped duodenum usually descends to the fourth lumbar vertebra, and seems to occur in foetal life when the ascending colon obstructs the way. The V-shaped duodenum usually descends to the fifth lumbar vertebra, and occurs when there is plenty of room and no obstruction by the descent of the ascending colon.

The lengths of the parts vary in the two types thus (measured from fifteen subjects):

Peritoneal Relations of the Duodenum.—The duodenum is included among the extra-peritoneal viscera. In the foetus it is completely invested, but the two layers of its mesentery have been separated or perhaps appropriated by the rapidly growing kidneys, and its posterior surface has adhered to the posterior abdominal wall. Its visceral layer has become parietal peritoneum. To get at this peritoneum it is necessary, on the cadaver, to practise certain manipulations: to disclose the initial superior parts, draw the hepatic flexure of the colon down and to the left, and lift up the anterior margin of the liver. The pylorus and supe-
rior curve of the duodenum can be seen attached to the liver by a ligament in which can be felt three cords, the lig. hepato-duodenale, and to the gall-bladder by a simple fold, the lig. cystico-duodenale.

Now pull toward the left this superior curve of the duodenum, and a deep space is formed bounded above by the right lobe of the liver. Below this is the right kidney, and to the left a series of organs all bound together by the same layer of peritoneum. The peritoneum covering the anterior surface of the right kidney passes from right to left, above, upon the vena cava inferior, thence behind an orifice, foramen of Winslow, into a large cavity which cannot be seen, the atrium bursae omentalis (Fig. 635). As this layer covers the vena cava it passes to the posterior surface of the liver, and is the lig. hepato-renale. A little lower than this, where the vein is covered by the superior angle of the duodenum, the peritoneum from the kidney covers the right and anterior surface of the first portion and part of the surface of the descending portion, running below into the gastro-colic part of the great omentum. Often the renal peritoneum passing to the first part of duodenum is raised into a fold, from the summit of the kidney to the summit of the curve of the duodenum, called lig. duodeno-renale (Huschke). Finally, still lower, where the hepatic flexure of the colon crosses about the middle of the descending duodenum, the renal peritoneum passes directly over the hepatic flexure of colon and fixes it. Three organs are thus bound together by a continuous layer, hepatic flexure of colon, duodenum, and right kidney. In other cases the hepatic flexure and ascending colon present a mesentry; here the renal peritoneum loses itself on the right leaf of this mesentery, which now covers in the descending duodenum. To see another side of the descending duodenum, incise the two anterior layers of the great omentum along the inner side of the duodenum and upper side of the transverse colon. This will open the bursa omentalis (Fig. 616). The large peritoneal surface which forms the posterior wall of this sac covers the pancreas and the left side of the descending duodenum. The rest of the duodenum still remains concealed under thick coverings. To see
the transverse and ascending portions and duodeno-jejunal angle, displace the intestines in two ways. Seize the lower end of the omentum and turn it and the transverse colon up over the chest-wall; then push the coils of the small intestine below and to the left. There is now uncovered a large peritoneal surface formed above by the lower layer of the transverse mesocolon, on the right by a layer of peritoneum to cover the ascending colon, on the left by the right layer of the mesentery, and below by the ileo-caecal angle. Shining through this common layer one usually perceives a part of the duodenum, its inferior angle or transverse portion.

Sometimes none of it can be seen here; that means a low duodenum, and in order to disclose it, turn all the small intestines upward and to the right (Fig. 613). Then one sees perhaps a portion of the descending part, the pre-aortic part, and always the ascending part, and duodeno-jejunal angle, escaping from the mesocolon. It has been noticed that when the transverse colon is held vertically up above the body (the subject being supine) the transverse mesocolon forms a horizontal partition. It divides the peritoneal cavity into two chambers—a superior gastro-spleno-hepatic, and an inferior intestinal. The ceiling of the upper chamber is formed by the diaphragm, the sides by the inner surface of the short ribs, and the floor by the upper layer of the transverse mesocolon. The liver, spleen, and stomach form its contents. The inferior chamber is limited above by the lower layer of the transverse mesocolon, on the sides by the ascending and descending colons, below by the iliac fossae, while the middle of this floor has been broken open to allow free communication between abdomen and pelvis. This chamber contains small intestines. The duodenum makes a bas-relief on the posterior walls of these two stories. The superior angle and a part of the descending portion is in the upper one; the rest of the descending portion, all the pre-aortic and ascending portion, and often the duodeno-jejunal angle, belong to the inferior story. Sometimes the duodeno-jejunal angle is in the thickness of the mesocolon forming the partition.

To describe the duodenal peritoneum of the lower chamber, reverse the great omentum as before, isolate the mesentery and hold it tense, then follow the course of its two layers. The left layer at first covers the part of the duodenum situated to the left of this mesentery and then proceeds to lose itself below in the right leaf of the sigmoid mesocolon, passing over the inferior mesenteric vessels; to the left it is continuous with the left prerenal peritoneum and right layer of peritoneum covering the descending colon; farther above, this layer passes over the left surface of the duodeno-jejunal angle and is continued into the inferior layer of the transverse mesocolon. The right leaf of the mesentery covers the duodenum to the right of this root and continues to cover the ascending colon; below it covers the ileo-caecal angle. Above, it passes upon the inferior layer of the transverse mesocolon and on the right surface of the duodeno-jejunal angle. Sometimes the two leaves of the mesentery embrace the duodeno-jejunal angle, and, instead of immediately reuniting beyond, they leave a space between, forming the orifice of the duodeno-jejunal fossa. The duodenum is crossed by two mesenteries, the second portion by the transverse mesocolon, and the third or fourth portion by the root of the mesentery.

The first part of the duodenum is almost completely covered by peritoneum derived from the two layers of the lesser omentum. Only a part of its posterior surface near the vena cava and neck of the gall-bladder is uncovered. The supracolic part of the descending portion has no posterior covering. Its right and anterior surface are covered by peritoneum from the anterior surface of the right kidney; its left side is covered by peritoneum of the lesser sac. Next on its anterior surface is a non-serous region corresponding to the interspace between the layers of the transverse mesocolon. The infracolic part of the second portion is covered by the right leaf of the mesentery.

A part of the pre-aortic portion has only an anterior covering from the right leaf of the mesentery. Depending on the position of the radix mesenterii and
of the duodenum, the remaining parts would be covered anteriorly by the left leaf of mesentery until the intestine is called jejunum, when it is wholly invested by mesentery.

The different layers of mesocolon cannot be regarded as forming any covering in the above list, because their attachments are all secondary.

A persistence of the mesoduodenum is normal in many animals, abnormal in man.

Ligaments of the Duodenum.

These are peritoneal folds connecting it to neighboring viscera or to the posterior abdominal wall.

1. Lig. suspensorium duodeni or lig. hepato-duodenale is the right edge of the lesser omentum, and passes from the hilus of the liver to invest by two layers the first portion of the duodenum, except a part of its posterior surface.

2. Lig. cystico-duodenale, from the neck of the gall-bladder to the superior curve of the duodenum.

3. Lig. duodeno-renale, triangular in form, from the right surface of the superior curve of the duodenum to the summit of the right kidney. The lig. hepatorenale is posterior to this one.

4. On the left of the descending duodenum, where the left layer of the mesentery runs into the lower layer of the transverse mesocolon or into prerenal peritoneum, one or two ligaments may limit certain fossae: they are lig. duodeno-mesocolica.

For duodenal fossae, see p. 994.

Relations of Duodenum.

The duodenum, occupying a fixed position against the posterior abdominal wall, comes into relation with all the abdominal organs except the spleen, which is fixed in the left cupula of the diaphragm. We may describe the relations with (1) Movable organs of the abdominal cavity, (2) Fixed organs of the posterior abdominal wall, (3) Lumbar skeleton.

(1) The relation with movable organs can be determined at once on opening the cavity. The stomach, in its empty state, touches by its antrum pylori the duodeno-jejunal angle (Braune), (Fig. 634). This occurs behind the posterior wall of the stomach, and the two are separated by the transverse mesocolon. If the stomach be distended the pylorus is deflected farther to the right, and the above relation is lost.

The hepatic flexure of the colon passes over the lower part of the anterior surface of the right kidney, and the beginning of the transverse colon over the middle part of the descending duodenum, as we have seen. The movable small intestines, being included in the ring of the colon, cover the duodenum as it lies in the lower chamber, and so render it almost inaccessible.

(2) The relations with fixed organs are with liver, the two kidneys, and the pancreas. The first and second portions are related to the liver and neck of gall-bladder. An impressio duodenalis is not always made on the quadrate lobe, although the first part of the duodenum passes under it. The initial curve is fixed at the inferior vena cava and neck of gall-bladder where the peritoneum is broken and the investment is incomplete. The impressio duodenalis is on the inferior surface of the right lobe to the right of the gall-bladder, to the left of the renal impression, and behind the colic impression.

In respect to the kidneys, not all authors speak of the left as being related. Luschka has always found the ascending duodenum related to the left kidney, as well as the descending duodenum to the right kidney, but the two duodenal parts always behave differently to their respective kidneys.

The descending duodenum is thrown strongly backward on the right of the lumbar column, and immediately meets the right kidney and suprarenal capsule as they all leave the liver. It then rests on the inner margin of the anterior surface
of the kidney and on the renal vessels at the hilus. Sometimes it only abuts against the inner margin, not covering its surface at all. This is thought to be due to a changed position of kidney and not of duodenum. The adhesion by connective tissue between the duodenum and kidney is especially close where the hepatic flexure crosses the kidney and then crosses the duodenum as transverse colon (Fig. 636).

In case the duodenum descends very low to the fifth lumbar vertebra, it then borders the lower extremity of the kidney. The relations of the ascending por-

![Diagram showing relations of duodenum to both kidneys.](image)

**Fig. 636.**—Diagram to show relations of duodenum to both kidneys.

tion with the left kidney are much more variable. A light traction from left to right displaces them. There are no adhesions, and the ascending duodenum glides easily over the subjacent tissue.

The annular or the U-shaped duodenum usually overlies the inner margin of the lower third or half of the left kidney; with the V-shaped duodenum, only the ascending portion or the duodeno-jejunal angle may touch the lower part of its inner margin. *Ureters* and *splanchnic vessels* are covered on the two sides by the duodenal arch.

Between the duodenum and *pancreas* there exists not only a relation of contiguity but one of continuity of tissue, which is explained by the duodenal origin of the pancreas. The head of the pancreas fills the space limited by the duodenal arch and then escapes as the neck by the opening of the intestinal ring. It is to be noted that the head is always proportional in extent to the duodenum, and assumes the form allowed by that intestine. In the adult the head of the pancreas embraces the duodenum much as the parotid gland embraces the ramus of the lower jaw. It advances in front and behind, covering about one-half of the circumference of the intestinal wall, generally more anteriorly than posteriorly.

The second portion is much more enveloped than any other. Union between the intestine and pancreas is established by cellulo-fibrous tissue, by pancreatico-duodenal vessels, by excretory ducts, and perhaps by longitudinal muscular fibres from the intestines which run between the lobules of the gland. Verneuil and Treitz believe the duodenum holds the pancreas in place and not *vice versa*.

By lifting all the viscera from the abdominal cavity, the vertebral column with its *prevertebral vessels* are disclosed behind the duodenum. There is the aorta, often a little to the left of the median line, which nearly always divides
at the fourth lumbar vertebra into its two primitive iliaces. A little to the right is the inferior vena cava, having just received the two common iliace veins. It also receives, behind the descending and ascending part of the duodenum, the renal veins—the right on the level of the lower part of the second lumbar vertebra, and the left a little higher on the level of the upper part of the same vertebra, having passed in front of the aorta.

The superior hepatic curve of the duodenum rests on the vena cava at the first lumbar vertebra right side. The descending portion covers about the two external thirds of the anterior surface of the vena cava and the right renal vessels.

The horizontal portion of the duodenum in the U-form applies itself in one part to the vena cava, and in another to the aorta, and sometimes passes over the common iliace. In the duodenum in the V-form the inferior angle lies upon the vena cava to the right of the aorta, then the ascending portion crosses the aorta sharply, from right to left, then borders it on the left and crosses the left renal vein and ends in the duodeno-jejunal angle.

The ascending portion in the U-form runs along the left surface of the aorta and finally over the left renal vein as the above. 

(3) Relations to the Lumbar Column.—By fixing the duodenum with pins while in situ, Jonnesco examined thirty subjects and found that the first portion of the duodenum lies to the right of the first lumbar vertebra. Its pyloric end in the median line is on the level of the inferior extremity of this vertebra, and it is directed up to the right and backward to reach the upper border of the same vertebra.

The pre-aortic portion, or inferior angle, reaches a variable point; in children, the superior border of the fourth lumbar, or the disk between it and the third. In adults with the duodenum in U-form, this pre-aortic portion moulds itself over the convexity of the fourth lumbar vertebra in 12 out of 20 cases. In some cases it passes over the fifth vertebra. In the duodenum in V-form the inferior angle applies itself most often to the right of the column, and the lower border of the fourth lumbar vertebra, in 5 out of 8 cases. Again it may go to the side of the fifth lumbar three times in 8 cases.

There may be three types: \( \text{high type} \), corresponding to the superior border of the fourth, or articulation between it and the third, seen in the child; \( \text{middle type} \), to the body of the fourth lumbar; \( \text{low type} \), to the body of the fifth lumbar, confined almost wholly to the V-type.

The duodeno-jejunal angle corresponds to the left of the vertebral column, may be to the first lumbar vertebra (infantile type), or to the second (adult type in U or V). In the first case the angle approaches the median line, in the latter it is thrown to the side of the column.

**Relations of Duodenum in Detail.**

**Superior Hepatic Curve, First Portion.**

*Above and in front:*
- Quadrate lobe of liver;
- Neck of gall-bladder;
- Foramen of Winslow;
- Hepatic artery.

*Behind:*
- Common bile-duct;
- Vena portae;
- Gastro-duodenal artery;
- Vena cava inferior (at summit of curve);
- First lumbar vertebra (on the left).
Below:
Neck of pancreas;
Head of pancreas.

Descending, or Second Portion.

Anteriorly:
Right lobe of liver (impressio duodenalis);
Right end of transverse colon;
Two layers of transverse mesocolon;
Small intestine;
Right leaf of mesentery.

Posteriorly:
Right kidney and suprarenal capsule (at times);
Structures at hilus;
Common bile and pancreatic ducts;
Vena cava inferior;
Spermatic vessels.

Internally:
Head of pancreas;
Pancreatice-duodenal vessels;
Common bile and pancreatic ducts;
First, second, third, fourth, or fifth lumbar vertebrae.

Pre-aortic, or Third Portion.

Superiorly:
Head of pancreas;
Superior mesenteric vessels.

Anteriorly:
Root of mesentery;
Right and left layers of mesentery;
Superior mesenteric vessels;
Small intestine.

Posteriorly:
Vena cava inferior;
Aorta;
Crura of diaphragm;
Third or fourth lumbar vertebra.

Ascending, or Fourth Portion.

Anteriorly:
Antrum pylori (at times);
Transverse colon;
Transverse mesocolon (lower layer);
Small intestine;
Left layer of mesentery.

Posteriorly:
Left Psoas muscle;
Left renal vessels;
Spermatic vessels;
Lower part of inner edge of left kidney.
Internally:
Head and neck of pancreas;
Aorta;
Fourth, third, and second lumbar vertebrae;
(Third, second, and first in child).

Terminal, or Fifth Portion.

Superiorly:
Body of pancreas.

Anteriorly:
Duodeno-jejunal angle;
Left layer of mesentery.

Exterrnally:
Inner margin of left kidney.

Means of Fixation.—Neither peritoneal adhesions nor peritoneal ligaments really fix an organ; if the latter ever does, it is because it contains vessels and nerves and cellular tissue between its layers.

The means here are—1. Biliary and pancreatic ducts. 2. Arteries which are the conductors and support of fibro-nervous tissue. 3. Suspensory muscle of Treitz supporting the duodeno-jejunal angle. 4. A cellular fold under the pancreas. (Treitz.)

1. The ducts of the two glands, common bile-duct and the pancreatic, contribute to the fixation of the duodenum, yet the lig. hepato-duodenale must render service in resisting a downward pull, whereby the ducts would be stretched and their functions disturbed.

2. Two abdominal arteries are important in fixing the duodenum to the posterior wall: the coeliac axis above it and superior mesenteric above and in front, which have retained their original positions of foetal life. There is a complete anastomosis or arterial circle between these vessels, connecting the posterior abdominal wall to the liver, stomach, pancreas, duodenum, and spleen.

3. Fibro-nervous investments accompany the arterial circle formed of cellular tissue and sympathetic nerve-plexuses. They have two rôles: first, innervation of the vessels, and secondly, support. The coeliac and solar plexuses support as one the duodenum and its neighboring organs the liver, stomach, and pancreas.

In 1853 Treitz described a muscle running from the duodeno-jejunal angle to the diaphragm. Many have since described it for him. If the beginning of the jejunum be pressed down, after turning up the stomach and transverse colon, a ridge of peritoneum will be seen to extend from the duodeno-jejunal angle up under the pancreas to the left crus of the diaphragm. This ridge is called the ligament of Treitz. The original article1 reads in substance thus—

"Raise the pancreas and detach it from the diaphragm. The duodeno-jejunal angle is seen attached to the posterior abdominal wall by a muscle (Fig. 637). This muscle is small and triangular and rises by its base from the superior border of the duodeno-jejunal curve and from a part of the ascending duodenum. It passes toward the aortic orifice of the diaphragm and near its centre continues into a tendon which becomes more narrow and loses itself in the tendinous tissue surrounding the superior mesenteric artery and aortic trunk, enveloping the ganglia and nerves of the coeliac plexus. By traction these fibrous bands can be seen connected with the inner pillars of the diaphragm, and commonly with the right border of the oesophageal orifice. All subjects possess it; it is best developed in muscular individuals and with a low-placed duodenum. Its tendon is 1.5 mm. long; the muscle 1 mm. thick. As to its function, it does not merit the name Levator duodeni; its action is of little importance as a muscle; it plays the rôle of a suspensory ligament and ought to be called Musculus suspensorius duodeni."

The muscle is continuous with the longitudinal muscular layer of the duodenum and is stronger the older the subject.

1 Prager Vierteljahreschrift, 1853, s. 113.
Treitz indicates a cellular membrane (Fig. 637) stretching between the superior mesenteric artery on one side, the pylorus, duodeno-jejunal angle, and concavity of the duodenum on the other, which forms a floor to the posterior surface of the pancreas and represents the foetal mesentery of the duodenum. He says on account of its tenacity it is unable to offer any fixation.

Such are the means of fixation in general. The duodenal ring is fixed in all its length, but unequally; it is suspended by two fixed extremities. Its superior hepatic angle is fixed by the total of organs attached to the liver and by the thick cellular tissue which fastens it to the inferior vena cava. There are also the structures forming the hepatic pedicle, artery, duct, and portal vein, all surrounded by fibro-nervous layers and all united into one by the serous membrane forming the lig. hepato-duodenale. Finally, the fibro-nervous tissue contained in the lig. cystico-duodenale serves to render the first part of the duodenum solid to the liver. The liver is fixed, not by peritoneal folds, as is commonly said, but by a thick cellular tissue and numerous subhepatic veins emptying into the inferior cava—nailed, so to speak, to the posterior abdominal wall. By such attachment to the vena cava and liver, the superior angle is secure.

The duodeno-jejunal angle is fixed by the muscle and ligament of Treitz. When this angle penetrates the thickness of the transverse mesocolon its fixation is still more assured. The branches of the superior mesenteric artery given to this angle reinforce the support. More than the ends of the duodenal arch must be supported or its lower part would separate from the posterior abdominal wall and come forward on a hinge-movement. As long as nothing presses this part of the duodenum backward this forward movement does occur, as in early human embryos or in case of a mesoduodenum, as in many animals.

Normally the adult human duodenum cannot separate from the posterior wall, owing to many agencies which come, in turn, to hold it down.

The descending duodenum is fixed to the inferior vena cava and right kidney by thick cellular tissue. This is further strengthened by the hepatic flexure and transverse colon, which apply themselves directly to the kidney and duodenum.

The pre-aortic portion is fixed by two agents—(a) by fibrous tissue between it and the aorta and vena cava inferior; (b) by the superior mesenteric artery surrounded by its fibro-nervous tissue, which forms the root of the mesentery and presses this part of the duodenum down upon the aorta. So the mesenteric artery and aorta, passing one behind the other, constitute a sort of vascular press, lessening the calibre to what may be called the isthmus of the duodenum.

The ascending portion is much less fixed than any other part to the posterior wall and left kidney. It is easily displaced from left to right, and peritoneal covering is its sole agency of fixation.

Résumé.—The duodenal ring is fixed against the posterior abdominal wall, or, better, against the fixed organs which cover it. This fixity is assured in part by the vascular system and by the fibro-nervous layers connected, and in another part by the muscle of Treitz.
Jejunum and Ileum (Intestinum mesenteriale).

Following the duodenum, about the upper two-fifths of the remaining small intestine is called jejunum and the lower three-fifths ileum. There is no morphological line of distinction between these two, but there is considerable difference between the beginning of the jejunum and end of ileum. The diameter of the first is about one and a half inches; of the latter, one and one-fourth inches; the walls of the jejunum are thicker and a given length weighs more than the same of the ileum; the character of the mucous membrane and of the contents markedly changes, but very gradually. The ileum possesses none or poorly-formed valvulae conniventes. The jejunum is usually in the umbilical region and left iliac fossa, while the coils of the ileum are more on the right side and right iliac fossa and true pelvis. Both these parts of the intestine retain the mesentery, which the duodenum does not.

There is but little fixation to the loops of the small intestine; the mesentery allows the freest motion. Every moment the coil must accommodate itself to changes in form and position of the peritoneal cavity or be prepared to fill some hole. Contraction of the diaphragm and abdominal muscles, the filling and emptying of viscera, presence of tumors, position of body, must all occasion changes of position in the small intestines. With this great motility, no definite shape can be ascribed for the coils, but frequently the upper loops of the jejunum are transverse and the lower of the ileum are more vertical.

The terminal part of the ileum is more fixed than any other, as its mesentery passing over the right Psoas muscle is very short. At the point of transition from the duodenum to the jejunum or from the small to the large intestine the various fossae have been noticed (p. 994).

The vitelline duct coming from the original convexity of the intestinal loop (Fig. 588) may persist in adult life; it is then called Meckel's diverticulum. It is a blind intestine, having the same layers as the ileum, with the lumen of which it directly communicates. It is two or three inches long (one-half to seven inches), and rises about forty-three inches from the ileo-colic junction (from one to ten feet); originally it passes toward the umbilicus, but usually hangs free in the cavity. It may be connected with the umbilicus or other points by a solid band, which attains great firmness and is the enlarged remains of the omphalo-mesenteric vessels. It may be conical, cylindrical, or hour-glass in shape. It occurs about once in fifty cases, and may cause surgical complications.

Structure of the Wall of the Small Intestine.—Like the stomach, the wall is composed of four layers, serous, muscular, submucous, and mucous. It is much thinner than that of the stomach, only \( \frac{3}{4} \text{ mm.} \) thick.

The external or serous coat is peritoneum, which surrounds the whole of the ileum and jejunum except along the little interspace left at the mesenteric border of the intestine. Here a sort of linear hilus is left between the two layers where vessels, nerves, veins, and lymphatics have their entrance or exit. In case of the duodenum, each part is covered to a different degree.

The muscular coat consists of two layers; as usual for the alimentary canal, the external is made of longitudinal fibres, and the internal of circular fibres. The longitudinal fibres are best developed at the beginning of the duodenum and end of the ileum, and are here closely attached to the serous coat. They are most marked on the free border of the intestine, and may be wholly lacking on the mesenteric attachment. The circular set is three times thicker than the longitudinal, and consists of complete muscular rings which are pressed so closely together as to only leave clefts for the passage of vessels and nerves to deeper parts. This double coat gets thinner below, is pale, and made of unstriated muscular tissue. It produces peristalsis, by which food is pushed onward.

The submucous coat acts as a bed for the mucosa, is connected more closely with it than with the muscular coat, and is made of areolar tissue. Here are lymphatic vessels and nerve-plexuses, and the blood-vessels divide up for the mucosa.
The mucous membrane is thick, red, and highly vascular at the upper part of the intestine, but paler and thinner below. Its inner surface is shaggy like velvet; this is due to the presence of minute processes called villi. Next the submucous coat is a layer of unstriped muscle fibres, the muscularis mucosa. This thin layer from the sheep makes the "catgut" of commerce. Internal to this is a quantity of retiform tissue containing goblet-cells and migratory leucocytes supporting tubular glands, blood-vessels, nerves, and lacteals. Most internally the mucosa is covered by a single layer of columnar epithelial cells resting upon a basement membrane. The prismatic cells contain granular protoplasm and oval nuclei. The free ends of the cells are invested by a cuticular zone or basilar border, a well-defined band exhibiting a fine vertical striation. Some interpret these as parallel canals for absorption of chyle.

The mucous membrane presents in its different parts the following structures:

Valvulae conniventes;
Villi;
Intestinal true glands
{ Glands of Lieberkühn;
Glands of Brunner;
Solitary glands;
Agminated glands, or Peyer’s patches.

Valvulae conniventes (valves of Kerkring, 1670), who gave the incorrect name, conniventes (connivère, to close the eyelids) (Fig. 638) are permanent crescentic folds of mucous membrane and submucosa; each contains two layers of mucous membrane, placed back to back and separated by the submucosa. They contain no part of the muscular coats, and are not obliterated by distention of the intestine. They extend transversely across the axis of the tube for about one-half or two-thirds of its circumference. Some form complete circles and others spirals; the spirals rarely may extend two or three times around the internal circumference. This is of interest, as a spiral valve is the characteristic of the intestine of certain fishes—e. g. the
shark family. The large folds project about one-third inch into the lumen, and often connect at one end obliquely with a smaller fold. Sometimes a valve terminates abruptly, or it bifurcates at one or both ends. They are so close that in a relaxed condition they cover the intestinal surface like roof-tiles. These valves are most abundant in the duodenum and jejunum; they decrease and disappear at the lower end of the ileum. Their total number is 800 or 900. They begin with the commencement of the descending duodenum, there being usually none in the first portion. Just beyond the point of entrance of the bile and pancreatic ducts they are very large and regular and closely packed. About two feet from the lower end of the ileum they cease. From this point up to the middle of the jejunum they are indistinct and irregular, smaller, and farther apart. They are seen at their best from the lower part of the descending duodenum through the upper half of the jejunum. Their function is to retard the passage of food and to afford an extensive absorptive surface.

The villi are minute vascular processes, consisting entirely of tissues of the mucosa, projecting from every part of the inner surface of the small intestine
over the valvulae conniventes as well as between them (Fig. 639). They give to
the surface its velvety appearance. Between the bases of the villi, wherever they
are, the mouths of the glands of Lieberkühn are seen (Figs. 640 and 642). They
are largest and most numerous in the duodenum and jejunum, resembling the
valvulae conniventes in distribution. They are smaller and fewer in the ileum,
and stop abruptly at the ileo-cecal orifice. There are none in the large intestine.
They measure .5 to .7 mm. in length, and are present to the number of about
four millions (Krause); 10 to 18 per sq. mm. in the upper intestine, and 8 to 14
to the same space in the ileum. They are apt to be leaf-shaped in the duode-
umum, tongue-shaped in the jejunum, and filiform in the ileum.

Structure of the Villi (Fig. 641).—The structure of the villi has been studied
recently by many eminent anatomists. We shall here follow the description of
Dr. Watney,\(^1\) whose researches have a most important bearing on the physiology
of that which is the peculiar function of this part of the intestine, the absorp-
tion of fat.

The essential parts of a villus are—the lacteal vessel, the blood-vessels, the
epithelium, the basement membrane and muscular tissue of the mucosa, these
structures being supported and held together by retiform lymphoid tissue.

These structures are arranged in the following manner: situated in the centre
of the villus is the lacteal, terminating near the summit in a blind extremity;
running along this vessel are unstriped muscular fibres; surrounding it is a plexus
of capillary vessels, the whole being enclosed by a basement membrane, supporting
columnar epithelium. Those structures which are contained within the basement
membrane—namely, the lacteal, the muscular tissue, and the blood-vessels—are
surrounded and enclosed by a delicate reticulum which forms the matrix of the
villus, and in the meshes of which are found large flattened cells, with an oval
nucleus, and, in smaller numbers, lymph-corpuscles. These latter are to be
distinguished from the larger cells of the villus by their behavior with reagents, by
their size, and by the shape of their nucleus, which is spherical. Transitional
forms, however, of all kinds are met with between the lymph-corpuscle and the
proper cells of the villus.

The lacteals are in some cases double, and in some animals multiple. Situated

\(^1\) Phil. Trans., vol. clxvi. pt. ii.
in the axis of the villi, they commence by dilated caecal extremities near to, but not quite at, the summit of the villus. The walls are composed of a single layer of endothelial cells, the interstitial substance between the cells being continuous with the reticulum of the matrix.

The muscular fibres are derived from the muscularis mucosae, and are arranged in bundles around the lacteal vessel, extending from the base to the summit of the villus, and giving off laterally, individual muscle-cells, which are enclosed by the reticulum, and by it are attached to the basement membrane.

The blood-vessels form a plexus between the lacteal and the basement membrane, and are enclosed in the reticular tissue; in the interstices of the capillary plexus, which they form, are contained the cells of the villus.

These structures are surrounded by the basement membrane, which is made up of a stratum of endothelial cells, and upon which is placed a layer of columnar epithelium. The reticulum of the matrix is continuous through the basement membrane (that is, through the interstitial substance between the individual endothelial cells) with the interstitial cement substance of the columnar cells on the surface of the villus. Thus we are enabled to trace a direct continuity between the interior of the lacteal and the surface of the villus by means of the reticular tissue, and it is along this path that, according to Dr. Watney, the chyle passes in the process of absorption by the villi. That is to say, it passes through the interstitial substance between the epithelium cells, through the interstitial substance of the basement membrane, the reticulum of the matrix, and the interstitial substance between the endothelial plates of the lacteal, all which structures have been shown to be continuous with one another, and, being probably semifluid, do not offer any obstacle to the passage of the molecular basis of the chyle.

Among the structures of the intestinal wall called glands there are two kinds—true and false; the latter belong to the lymphatic system. The true glands are those of Lieberkühn and Brunner.

The follicles, crypts, or glands of Lieberkühn (Figs. 643 and 644) are very numerous, forming an almost continuous layer of tubular depressions throughout the intestines, large and small. They are in every part of the small intestine, opening between the villi (Figs. 640 and 642). Their small circular mouths may be seen by the aid of a lens. They occupy nearly the whole depth of the mucosa, are upon the valvulae conniventes, their blind ends approaching nearly perpendicularly the muscularis mucosae. They consist of thin tubes, whose walls are made of basement membrane, lined by the columnar epithelium from the free surface. Many of these cells change to spherical secreting cells, some of which become goblet-cells (Fig. 644). They are 2 to 3 mm. long and about .04 mm. in diameter.

The duodenal or Brunner's glands are limited to the duodenum and first part of the jejunum. They are most numerous in the first part of the duodenum, within one or two inches of the pylorus. They are small compound tubular glands, consisting of a number of tubular alveoli opening into a slender duct, much like
the salivary glands of the mouth, which are more compact. They are probably direct continuations and higher specializations of the pyloric glands. They are situated in the submucosa or in part in the mucous membrane. Their ducts penetrate the muscularis mucosae, pass between the glands of Lieberkühn and open upon the inner surface of the intestine, or in some cases into the bases of the crypts.

The solitary glands (Fig. 645) are found scattered throughout the mucous membrane of the small intestine, but are most numerous in the lower part of the ileum. They are small, round, whitish and slightly prominent bodies 6 mm. to 3 mm. in diameter. They are formed on the mesenteric as well as free border, between and upon the valvulae conniventes. The free surface of the follicle may have villi upon it, but at the centre or cupola they are lacking. Each gland is surrounded irregularly by the openings of the glands of Lieberkühn. These so-called glands have a structure similar to that of a lymph-node, consisting of dense retiform tissue closely packed with lymph-corpuscles, and permeated by fine capillaries. They have no ducts. The interspaces of the retiform tissue are continuous with larger lymph-spaces at the base of the gland by which they communicate with the lacteal system, or they may even hang into a lacteal sinus which may nearly surround the nodule. The base of the nodule is in the submucous tissue. They penetrate the muscularis mucosae and enter the mucous membrane, where they form slight projections of its epithelial layer.

Agminated glands or Peyer's glands (1677) may be regarded as aggregations of the solitary glands, forming circular or oval patches (Fig. 646). They number from twenty to thirty, and vary in length from one-half to four inches; in width from one and a half to two inches. They are largest and most numerous in the lower two-thirds of the ileum. In the lower part of the jejunum they are small and few and of a circular form. They are occasionally seen in the lower duodenum. They are placed lengthwise to the intestine, covering that portion of the tube opposite the attachment of the mesentery, hence to see them well open the bowel along its mesenteric attachment.

Each patch is formed of a group of lymph-nodes which are similar to the solitary glands above described. Each follicle becomes somewhat pyramidal, due to pressure, and they lose much of their individuality, being most distinct along the

The image contains diagrams labeled with letters corresponding to parts of the intestine. Diagrams are not transcribed here.
THE ORGANS OF DIGESTION.

outer boundary. The surface of a patch is usually free from villi; it is surrounded by a row of the crypts of Lieberkühn.

They are best marked in young subjects, where as many as 45 have been observed; they become indistinct in middle life and even disappear in old age. Their resemblance to lymph-glands is seen in any infectious disease of the intestines, especially in typhoid fever, where they may ulcerate and perforate to the peritoneal cavity, causing fatal haemorrhage.

They have a large vascular supply which forms an abundant plexus around each follicle. This gives off fine capillaries, which, supported by the retiform tissue, converge toward the centre (Fig. 647). The lacteal plexuses, which are abundant throughout the small intestine, are especially so around the follicles of a Peyer's patch, often forming sinuses around them (Fig. 648).

Résumé.—The valvulae conniventes and villi are most abundant in the upper part of the small intestine.

Brunner's glands are mostly in the duodenum.

Solitary glands and Peyer's patches are most abundant in the lower part of the small intestine.

The crypts of Lieberkühn are abundant in both large and small intestines. The large intestine possesses the crypts of Lieberkühn and solitary glands.

Vessels and Nerves of the Small Intestine.

The arteries supplying the duodenum are the pyloric, the superior pancreatico-duodenal, from the gastro-duodenal, all of which come from the hepatic, and the inferior pancreatico-duodenal, from the superior mesenteric.

The jejunum and ileum are supplied by the superior mesenteric artery, the
branches of which, having reached the attached border of the bowel, run between the serous and muscular coats, with frequent inosculations to the free border, where they also anastomose with other branches running round the opposite surface of the gut. From these vessels numerous branches are given off which pierce the muscular coat, supplying it and forming an intricate plexus in the submucous tissue. From this plexus minute vessels pass to the glands and villi of the mucous membrane. The veins have a similar course and arrangement to the arteries. Each artery has only one vein. The lymphatics of the small intestine (lacteals) are those of the mucous membrane and those of the muscular coat. The lymphatics of the villi commence in these structures in the manner described above, and form an intricate plexus in the mucous and submucous tissue, being joined by the lymphatics from the lymph-spaces at the bases of the solitary glands (Fig. 648), and from this pass to larger vessels at the mesenteric border of the gut. The lymphatics of the muscular coats are situated to a great extent between the two layers of muscular fibres, where they form a close plexus, and throughout their course communicate freely with the lymphatics from the mucous membrane, and empty themselves in the same manner into the commencement of the lacteal vessels at the attached border of the gut.

According to Sappey the vessels from a villus have two functions, one set is to carry chyle and the other lymph. The former either contains chyle only or is empty. After the vessels have entered the mesentery, then they interchangeably carry chyle or lymph. The nerves of the small intestine are derived from theplexuses of sympathetic nerves around the superior mesenteric artery. Those nerves come from the coeliac plexus, the semilunar ganglia, and largely from the right vagus nerve. From this source they run to a plexus of nerves and ganglia situated between the circular and longitudinal muscular fibres (Auerbach's plexus) from which the nervous branches are distributed to the muscular coats of the intestine. From this plexus a secondary plexus is derived (Meissner's plexus), which is formed by branches which have perforated the circular muscular fibres. This plexus lies between the muscular and mucous coats of the intestine. It is also gangliated, and from it the ultimate fibres pass to the muscularis mucosae and to the mucous membrane.

The Large Intestine.

The large intestine extends from the termination of the ileum to the anal orifice. It differs from the small intestine in its larger size, more fixed position, saccular form and appendices epiploicae. It is about five or six feet in length or one-fifth that of the whole intestinal canal (Sappey 1.68 m.). Its capacity in moderate distention averages twenty-two ounces per foot, or seven and a half to eight pints for the whole length. Its circumference decreases from beginning to end, except at the ampulla of the rectum; it measures 28.5 cm. at its widest part, junction of colon and cæcum, 20.5 cm. at the end of the ascending portion, 14.5 cm. in the descending portion. Diameter varies from two and a half inches to less than one inch. By accumulation of fecal matter or gas the colon may be distended to double its normal size.

Sometimes in the fresh body of a robust suicide the descending colon or sigmoid flexure or even part of transverse colon may be contracted to the thickness of a thumb. The tube is hard and can scarcely be opened by inflation. It is not pathological, as coroners say, but a high degree of rigor mortis, which will disappear. In the greater part of the colon its external surface is very uneven from the presence of pouches or sacculæ, protrusions arranged in rows of three columns. These are separated by three ligamentous tapes about the width of the little finger.

In its course the large intestine describes a horseshoe-shaped arch which surrounds the convolutions of the small intestine. It begins in a blind sac in the right iliac fossa, ascends along the right posterior abdominal wall to the right hypochondrium, where it is in contact with the under surface of the liver. It here
bends to the left, and takes a transverse somewhat ascending course to the spleen. In the left hypochondrium it bends again and descends along the left posterior abdominal wall to the left iliac fossa, then becomes convoluted as the sigmoid flexure: it finally enters the pelvis and descends as the rectum along its posterior wall to the anus.

There are to be distinguished, then:
1. Cecum (intestinum cecum), or Caput coli;
2. Colon ascendens, or Right colon;
3. Hepatic flexure, or Flexura coli dextra;
4. Colon transversum;
5. Splenic flexure, or Flexura coli sinistra;
6. Colon descendens, or Left colon;
7. Flexura sigmoidea (Colon sigmoideum), or S. romanum.
8. Rectum (intestinum rectum).

Structure of the Large Intestine.

We find here the same four coats which have been seen in the canal above: serous, muscular, submucous, and mucous.

The serous coat is the peritoneal covering investing parts of the large intestine to a variable extent.

The cecum is completely invested. The ascending and descending colons in the adult have usually only a third of the posterior surface left bare. It is a question when to declare the folds near enough to call them a mesocolon.

Treves says a mesocolon may be expected on the left side in 36 per cent. of all cases, on the right side in 26 per cent.

The transverse colon is almost completely invested, having a proper mesocolon; the great omentum is attached to its anterior surface.

The sigmoid flexure has a mesocolon, and the upper part of the rectum has a mesorectum. In the second part of the rectum the peritoneum covers its anterior surface and parts of the sides; its third portion loses it altogether. The peritoneum covering the internal taenia along the colon, especially the transverse and after part, is thrown into many external pouches containing fat in well-nourished people; they are called appendices epiploicae, or omentula.

The muscular coat consists of an external longitudinal and an internal circular layer.

The longitudinal fibres are partly collected into three flat longitudinal bands, each about half an inch wide and one twenty-fifth inch thick. They are found on the cæcum and colon and each is called ligamentum or taenia coli. Between these bands the longitudinal layer is present, but very thin. On the appendix the layer is uniform. These bands spread out from the root of the vermiform appendix to the cæcum. Thence they can be traced as far as the rectum, where they form two bundles. The posterior band passes along the mesenteric attachment of the intestine; another, the largest, runs along the anterior border of the ascending and descending colons and on the transverse colon corresponds to the attachment of the great omentum. The third or internal band runs along the inner borders of the ascending and descending colons, but becomes inferior on the transverse colon.

The three bands are about one-half shorter than the real walls of the intestine and so form sacculi or haustra (buckets). If the bands be dissected away the sacculi will be wholly effaced and the colon becomes much elongated and cylindrical. The transverse constrictions seen on the outside of the intestine between the sacculi appear on the inside as sharp ridges.
which separate the pouches, cellulae, or haustra. The whole projection is made up of all the coats of the intestine and is called the plica or valvula sigmoidea (Fig. 649). A valve passes between two teniae where otherwise a transverse fold would exist. Only rarely do two or three valves lie in the same plane, so that they would be in position to effect a scissor-like motion and cut a mass of faecal matter into scybala or round balls.

The circular fibres form a thin continuous layer and are especially collected in the constrictions between the sacculi. In the rectum they form the Internal sphincter muscle.

The submucous coat is in the same position and serves the same purpose as in the small intestine.

The mucous membrane is pale, smooth, destitute of villi and raised into crescentic folds, separating the pouches and corresponding to the external constrictions separating the sacculi.

As in the small intestine, the mucous membrane consists of a muscular layer, the muscularis mucosae; of a quantity of retiform tissue, in which the vessels ramify; of a basement membrane and epithelium, which is of the columnar variety and exactly resembles the epithelium found in the small intestine. The mucous membrane of this portion of the bowel presents for examination crypts of Lieberkühn and solitary glands.

The crypts of Lieberkühn are tubular prolongations of the mucous membrane, arranged perpendicularly, side by side, over its entire surface; they are longer, more numerous, and placed in much closer apposition than those of the small intestine, and they open by minute rounded orifices upon the surface, giving it a cribriform appearance.

The solitary glands (Fig. 650) in the large intestine are most abundant in

![Diagram of solitary gland](image)

the cecum and appendix vermiformis, but are irregularly scattered also over the rest of the intestine. They are similar to those of the small intestine.

**Vessels and Nerves.**—The arteries supplying the large intestine give off large branches, which ramify between the muscular coats, supplying them, and, after dividing into small vessels in the submucous tissue, pass to the mucous membrane. Those arteries are the ileo-colic, colica dextra, colica media from the superior mesenteric, colica sinistra and sigmoidea from the inferior mesenteric.

The lymphatic vessels consist of two layers; the deep set lie under the glands of Lieberkühn, and the superficial forms a wide-meshed network which penetrates the submucosa in all directions. The lymphatics of the ascending, transverse, and descending colons open into the mesenteric glands, those of the sigmoid flexure into the lumbar glands.
The nerves which supply the caecum, ascending and right half of the transverse colon are sympathetic, coming from the superior mesenteric plexus derived from the coeliac plexus. Those which supply the left half of the transverse colon, the descending and sigmoid colon come from the inferior mesenteric plexus derived from the aortic plexus. In their course they accompany the arteries.

The caecum (cecum, blind) (Fig. 653) is the head of the colon, or that part of the large intestine situated below the ileo-caecal valve, some say below the ileum. Its length and breadth are never equal, the breadth being always the greater. The opinions vary thus—

The discrepancies are due largely to methods of measurement. Treves takes as the upper limit of the caecum the lower edge of the ileum. Berry states this is too short, and the upper limit of caecum is on the level of the ileo-caecal valve, or Struthers' "frenal furrows," which are continuations of the ileo-caecal valve. If these furrows cannot be seen externally, take as the upper limit an "approximation line," drawn transversely across the colon from a point midway between the upper and lower edges of the ileum. In 100 cases this gave Berry's figures, 6 and 7 cm., for average length and breadth. "Sex has no influence upon size, but it varies with age, being absolutely and relatively larger in the adult. Caeca of insane persons are apt to be abnormal" (Berry).

The caecum lies in the right iliac fossa above the outer half of Poupart's ligament, its point being at about the middle, immediately behind the anterior abdominal wall in front of the ilio-psos muscle (Fig. 578). Should it be long it may extend more or less into the pelvic cavity (Fig. 626).

Many statements are made as to its peritoneal relations. Bardeleben first stated it was wholly invested by peritoneum; Luschka, Treves, very positively, Struthers and Jonnesco all agree. Quain states that in 5 per cent. of cases the
peritoneal covering is not complete, but is reflected just below its upper end, leaving the upper part of its posterior surface uncovered and connected to the iliac fascia by areolar tissue. Berry has seen the same thing in 6 per cent. of cases. The reflected peritoneum never makes a true mesoaecum. It may have sufficient motility or length to enter a right inguinal or femoral hernia, and in rare cases a left one. According to Treves, any human caecum can be classified under one of four types (Fig. 652). In certain monkeys we see a primitive form

where the caecum is short, conical, and broad at the base, with its apex turned up and in toward the ileo-colic junction (Fig. 651, A). This type is seen early in the human foetus. Next it grows in length more than in breadth, and this type is seen in the human foetus in Fig. 651, B. As development goes on the lower part of the tube ceases to grow and the upper part becomes greatly increased, so that a narrow tube is formed hanging from a conical projection. The latter is the caecum, and the small tube the vermiform appendix. This is the fetal or infantile type (Fig. 652, A). It may persist throughout life. Treves found it

![Fig. 652. A, B, C, D, four types of human caecum. (Treves.)](attachment)
in adults to the extent of 2 per cent. The cæcum is conical, and the appendix rises from its apex in line with the axis of the colon. The three longitudinal bands of the colon start at the root of the foetal appendix about equidistant, and pass up over the cæcum and colon as described, dividing them into three rows of sacculations. The second type (Fig. 652, B) has substituted the conical cæcum for a more quadrate one. The appendix is in the centre of two sacculi of equal size instead of at the apex of a cone. There is an equal extent of intestine on each side of the anterior band. The higher apes have this type—e. g. gibbon. In the human subject it occurs in 3 per cent. The third type (Fig. 652, C) is the normal type found in man. The walls of the cæcum have grown at unequal rates. The right sacule and anterior wall, probably due to better blood-supply, have outstripped the left sacule and posterior wall. The appendix still rises from the true apex, the three bands still start from its root, but they are all now found to the left and posteriorly near the ileo-colic junction. A new or false apex has appeared, which really is the exaggerated convexity of the right sacule situated between the anterior and postero-external bands. This form occurs in 90 per cent., and hence is of great surgical importance, as it simplifies the location of the appendix. In the fourth type the condition of the third has gone still farther. The right sacule and parts to the right of the anterior band have excessive development, while the parts to the left of the band are atrophied. Here the anterior band runs to the inferior angle of the ileum, while the cæcum and the appendix seem to rise from the ileo-colic junction (Fig. 652, D). This occurs in 4 or 5 per cent.

Berry has gone over the same work and obtained nearly the same percentages, proving that in about 90 cases out of 100 the base of the appendix bears a definite relationship to the ileo-cecal junction.

Sometimes the cæcum is small and insignificant, may be enormous; may be rotated so the ileum passes behind and enters on the right side; or the left parts may be so developed that the ileum enters anteriorly.

Vermiform Appendix.—Starting from what was originally the apex of the tube, the inner and back portion of the cæcum, usually 1.7 cm. below the ileo-colic opening, is a famous narrow round part of the intestine called the appendix cæci, or, on account of its worm-like appearance, appendix vermiformis. This is first seen low down among the mammals, in the marsupial group, in the wombat. No sign of it again appears till the ichneumon and pig are reached, but not then is it a proper appendix. It is next seen in the lemurs and higher apes, as chimpanzee, orang, gibbon, and gorilla. Finally in man it is present as a functionless and dangerous structure. Its length, averaged from eleven authors, is 9.2 cm. Its extremes are 1 to 9 inches, or 3.1 cm. to 23 cm. It attains its greatest length between the twentieth and fortieth years (Berry). Its length compared to that of the large intestine is 1 to 10 in the new-born, and 1 to 20 in the adult. There is no relation between size of cæcum and length of appendix. Its diameter is 6 mm. at base and 5 mm. at apex.

The appendix has no set position. Treves considers it to pass most frequently up from behind the cæcum to the left behind the ileum and mesentery toward the spleen. Others regard this position as nearly abnormal. Turner of Russia finds it hanging into the true pelvis in 51 out of 83 cases, and transversely across the promontory in 20 more of those cases.

Berry gives order of frequency as: 1. Pelvic position; 2. Retro-cecal; 3. Internal cecal (toward spleen); 4. Variable.

The order of frequency found in this country by J. D. Bryant was most often "inward," then "behind cæcum," "downward and inward," "into true pelvis."

The explanation of an up-turned or down-turned appendix is probably to be sought in foetal life. If the distal end of the appendix gain adhesions with the

mesentery or abdominal wall when it is still high up beneath the liver, the cæcum will drag it down in an inverted position. If no such adhesions occur, then it will descend freely, and perhaps dip into the pelvis. It takes a somewhat spiral form, due to its short mesentery.

Relations to cæcum have been noted above under Cæcum, where the data are quite constant.

Relations to the anterior abdominal wall for clinical purposes do not agree. Clado draws two lines, one along the outer edge of the right Rectus, and another connecting the anterior superior spines of the ilia. The point where these intersect Clado uses as a guide to the base of the appendix, which brings it into the hypogastrium. McBurney draws an imaginary line from the right anterior superior spine to the umbilicus. His “point” is situated on this line two inches from the spine. This is used as a guide to the base of the appendix. This point is in the right iliac fossa.

Relations to peritoneum are that a mesentery is always present, but it does not extend the whole length of the tube, leaving the distal third or so free and completely covered by peritoneum. This meso-appendix is triangular and comes from the left leaf of the mesentery, and contains in its fold the posterior branch of the ileo-cecal artery, which is derived from the ileo-colic.

Its walls present the same layers as seen in the colon, and its whole mucous membrane is closely studded with solitary glands. It is usually hollow to its extremity and its lumen communicates with the cæcum by a small orifice often guarded by a valve.

Gerlach in 1847 described a “semilunar fold of mucous membrane guarding the appendico-cæcal orifice.” It was only .5 to 1 mm. high and was so turned as to cause retention of the normal secretion in the appendix. The existence of Gerlach’s valve is now doubted. It is inconstant and unimportant.

There is usually another bigger crescentic fold near the orifice (Fig. 654), but with no function of a valve.

According to Ribbert and Zuckerkandl the cavity of the vermiform appendix tends to undergo obliteration, not as a pathological process, but a physiological one. In children the lymph-follicles of the appendix are very numerous and close. After the twentieth or thirtieth year it is normal for them to atrophy. Obliteration of the process occurs to some degree in 99 cases out of 400 (25 per cent.); total obliteration in 3.5 per cent. (Ribbert). Or obliteration occurred in 23.7 per cent.; total obliteration in 13.8 per cent., and partial (distal half most common) in 9.9 per cent. (Zuckerkandl). It never occurs in new-born. After sixty years of age more than half are obliterated. It occurs more often in a short process, 5 to 6 cm. long. One can never tell by macroscopic appearance as to the presence of obliteration.

The pathology seems to be an involution-change in a functionless organ. There are no signs of inflammation or cicatrices. As a first step there is atrophy of the mucous membrane, and its glands disappear. The submucosa thickens and accumulates fat. The muscular coat is either unchanged or becomes hypertrophied. The adenoid tissue is finally lost. There are four authentic cases of absence of the appendix. For the fossæ of this region see p. 997.

The Ileo-colic, Ileo-caecal valve or Valvula Bauhini.

The end of the ileum passes obliquely upward and to the right, and opens into the large intestine on its postero-internal surface; it opens upon the summit of a plica sigmoidea which marks the junction between the cæcum and ascending colon.

This orifice appears as a transversely oblique or a double convex slit. It is often rounded on the left and presents a sharp apex to the right (Fig. 654). It is bounded by a valve having two semilunar segments, a colic and a cæcal one, which project into the lumen of the large intestine. The upper of these segments is more horizontal, the lower more concave and longer. At each end they
coalesce and are prolonged into *fræna* or *retinacula* of the valve. The segments are made by an invagination of parts of the wall of the ileum into those of the colon (Fig. 655). Each segment of the valve consists of two layers of mucous membrane continued around the free border, one from the small intestine and one from the large, including between them submucosa and circular muscular fibres; the longitudinal fibres and peritoneum are continued uninterruptedly across from one intestine to the other and do not enter their composition. If these two coats be incised and traction made on the ileum, these valves can be unfolded and drawn out of the colon, the ileum appearing to open into the intestine by a large funnel-shaped orifice. The opposed mucous surfaces of the segments looking toward the ileum are covered by villi and present the structure of the small intestine. In fetal life the other two surfaces possessed villi too, but by birth the latter have disappeared. The surfaces turned toward the large intestine present the follicles and glands of Lieberkühn peculiar to the large intestine.

The function of the valve is to prevent regurgitation of intestinal contents back into the small intestine. When the cæcum is distended, the segments are approximated. They act even in the cadaver, proving that muscular action is not essential. When in an experiment water was injected into the colon, not a drop passed through the valve; when the pressure was increased to a height of two or three metres the valves did not yield, but the walls ruptured. In intestinal obstruction there is evidence of a return of contents from the large intestine. This is probably due to a slow, gradual distention of the walls of the large intestine, and hence a relative insufficiency of the valve. High enemata may pass this valve in two out of three cases, but such a valve is regarded as imperfectly developed and incompetent from the first.
This valve has been named after nearly all the following men. It was discovered in 1573 by Varolius, who called it an operculum. Six years later Bauhin called it valcula. Fabricius in 1618 first tried its function by insufflation. Casserius, Tulpius, and Bartholin repeated the experiments. Morgagni in 1719 gave the best description. Winslow and Albinus followed him.

Colon.—As in the cæcum, the outer surface of the colon is prismatic and triangular. Four characteristics are observed: 1. Three teniae which start from the root of the appendix; 2. Three rows of sacculi between the bands; 3. Constrictions which separate the sacculi of each row; 4. Appendices epiploicae. The internal surface has a reverse conformation, the projections between the pouches being called piece sigmoideæ.

The ascending colon is smaller than the cæcum, with which it is continuous, and larger than the transverse colon. It is very short. It passes up through the right lumbar region into the right hypochondrium until it reaches the inferior surface of the right lobe of the liver to the right of the gall-bladder, the impressio colica. It is retained in contact with the posterior abdominal wall by peritoneum which covers its anterior surface and sides, its posterior surface being connected by loose areolar tissue with the fascia covering the Quadratus lumborum and Transversalis muscles, and with the front of the lower and outer part of the right kidney. An abscess of the right kidney could thus break through into the ascending colon and not wound the peritoneum. It is in relation in front with the abdominal wall and convolutions of the ileum. Sometimes the peritoneum nearly surrounds the colon and forms a short mesocolon. On the under surface of the liver in the region of the gall-bladder, the ascending colon forms a sharp angle from the posterior abdominal wall to the front and the left, becomes somewhat superficial, and continues into the transverse colon. This is the hepatic or right colic flexure, bound to the under surface of the liver by the lig. hepato-colicum.

The transverse colon is the longest part of the large intestine, averaging twenty inches, while the ascending colon is eight inches, and the descending, from the splenic flexure to the crest of the ilium, is eight and a half inches. It passes from the hepatic flexure in the right hypochondrium transversely and slightly upward from right to left along the anterior abdominal wall to the splenic flexure in the left hypochondrium (Fig. 626). Since the colon is longer than the width of the abdomen it describes an arch, transverse arch of the colon, with its convexity directed downward and forward.

It is the most movable part of the colon, for it has a very long mesentery, the transverse mesocolon, which allows it a variable position. Its usual position corresponds to the line separating the umbilical and epigastric regions. In four times out of five it is above the umbilicus. It is in relation by its upper surface with the under surface of the liver and gall-bladder, greater curvature of the stomach and lower end of the spleen; by its under surface with the small intestine; by its anterior surface with the great omentum and abdominal walls; by its posterior surface with the transverse mesocolon; on the right with the second part of the duodenum, and to the left of this with some convolutions of the small intestine. If this colon has a very direct and obliquely ascending course, the greater curvature of the stomach will be behind its left portion.

In some cases the transverse colon may present a V- or U-shaped bend descending as far as the pubes. These bends are always downward, abrupt, and angular. Treves thinks they are due to habitual distention or to congenital causes (Fig. 656). They are normal in many animals.

The descending colon is continuous with the transverse by the splenic flexure, 1 Mr. Treves states that, after a careful examination of one hundred subjects, he found that in fifty-two there was neither an ascending nor a descending mesocolon. In twenty-two there was a descending mesocolon, but no trace of a corresponding fold on the other side. In fourteen subjects there was a mesocolon to both the ascending and the descending segments of the bowel, while in the remaining twelve there was an ascending mesocolon, but no corresponding fold on the left side. It follows, therefore, that in performing lumbar colotomy a mesocolon may be expected upon the left side in 36 per cent. of all cases, and on the right in 26 per cent. (The Anatomy of the Intestinal Canal and Peritoneum in Man, 1885, p. 55.)
or left colic flexure, which is higher up and farther back than the hepatic flexure.

To this bend a fold of peritoneum is attached, rising from the diaphragm between the tenth and eleventh ribs. It is the phrenico-colic ligament, rather than "costocolic," as it does not touch a rib. The spleen happens to lie just above it, so it acts as a support to that organ though not connected with it, and thus receives a second name, sustentaculum lienitis (supporter of the spleen). The colon then descends along the outer border of the left kidney, then turns in a little, and descends to the crest of the ilium or to a point where the peritoneum begins to surround the intestine and form a mesocolon for the sigmoid flexure.

It has passed along the outer border of the Psoas muscle in front of part of the Quadratus lumborum, and more largely in front of the Transversalis muscle. The relations of the descending colon on the left side are much like those of the ascending on the right, only the former reaches a little higher and is placed more laterally, so it can be more easily reached through the posterior abdominal wall for the establishment of an artificial anus.

This colon is smaller and deeper than the ascending colon and more liable to have a mesocolon.

The sigmoid colon or flexure is in the left iliac fossa, commencing above at the iliac crest and ending below in the rectum at the brim of the true pelvis opposite the left sacro-iliac articulation, or just as often opposite the upper edge of the sacrum. In general it is described as an S-shaped curve in which can be distinguished an upper colic limb turned toward Poupart's ligament, and a lower rectal limb which hangs more or less into the true pelvis.

This first part usually passes downward, inward, and somewhat forward, approaching the anterior abdominal wall and outer part of Poupart's ligament. This portion may have peritoneum only in front and on the sides. The next part is more movable, its mesentery is about three inches long, and it constitutes the sigmoid loop proper. When it does not hang down into the pelvis, the bladder and rectum are distended and push it up, in rare cases as high as the umbilicus or even liver. This loop may lie in the iliac fossa outside the first part; if its mesocolon is short, it passes obliquely across the iliac fossa and is covered by small intestine.

The sigmoid mesocolon is inserted into a line running from the left at the crest of the ilium across the psoas muscle and left iliac vessels at right angles to the anterior surface of the sacral promontory, where it is continuous with the mesorectum (Fig. 614). In the left layer of this mesentery is the intersigmoid fossa (page 996). The position of the flexure in the new-born demands notice, for here the mesentery is very long and the flexure may reach over on the right to the cæcum. This flexure is usually filled with meconium.

**Relations of Large Intestine in Detail.**

**Cæcum.**

*Anteriorly:*
Anterior abdominal wall above outer half of Poupart's ligament.

*Posteriorly:*
Right ilio-psoas muscle; Origin of appendix.

Posteriorly:
Quadratus lumborum muscle;
Transversalis abdominis muscle;
Outer margin of Psoas muscle;
Lower part left edge of left kidney.

Superiorly:
Spleen;
Phreno-colic ligament.

Anteriorly:
Anterior abdominal wall;
Small intestines.

Posteriorly:
Left ilio-psoas muscle;
Posterior wall of pelvis;
Rectum.
The **rectum** constitutes the terminal portion of the intestinal tube. It received its name *intestinum rectum* from its straight course in animals. In the human subject its course is nearly vertical, but it presents four curves and should be called *intestinum curvum* (Lisfranc).

The ancient and much-copied method of description divides it into three parts. We hesitate to introduce a change in old nomenclature, but will mention those proposed and allow the reader to make his choice.

Treves in 1885 called attention to the fact that there was no demarcation between the sigmoid flexure and the first part of the rectum at the brim of the pelvis. So he concludes the intestines should be called sigmoid flexure until the mesocolon is lost, i.e. until it reaches the third sacral vertebra. This rectum, therefore, has the two lower parts of the three usually described and no mesorectum. Cunningham and Quain take for the rectum the upper two of the three usually described, the third being regarded as a separate part called **anal canal**.

*The rectum in three parts* is situated in the pelvic cavity and on its floor. It is attached to its posterior wall, whose curve it follows. Its inferior limit is a circular line separating the skin from the mucous membrane—the **anal orifice**. Its superior limit cannot be determined precisely; it is continuous with the sigmoid flexure, but there is only an arbitrary line of demarcation. This is the pelvic brim, most usually opposite the left sacro-iliac articulation, quite often the sacro-vertebral angle, or rarely on the right of the base of the sacrum. Superiorly, it is united to the sacrum by a fold of peritoneum, the **mesorectum**. Lower down the peritoneum only covers the sides and front, much as in the case of the descending duodenum (Fig. 657). Still lower down, at a height of about one inch above the prostate gland, it entirely abandons the rectum and is reflected upon the neighboring organs, making, according to sex, the recto-vesical pouch or the recto-vaginal and recto-uterine. The height of the recto-vesical pouch in the male is never more than 8 cm. above the anus. The height of the recto-vaginal in the female is always less, about 6 cm. **The length** of the rectum, measured along its anterior wall (in the body), is 18 to 22 cm., or about eight inches. Outside the body it measures 25 cm. The **calibre** varies according to circumstances.

When empty it is less than that of the other portions of the large intestine. When it contains a certain amount of faecal matter its middle portion is more or less dilated, but not to the size of the cecum. The calibre of the remainder, in general, is not circular. In the lower part of the rectum it presents a transverse slit, and the anterior and posterior walls lie upon each other, mainly from the pressure of the anterior organs forcing the rectum back on the sacrum and coccyx. Just at the turn of the rectum into its third portion, and especially
marked anteriorly at the apex of the prostate, is the largest part, the *ampulla* of the rectum.

The lowest inch of the rectum, the *anal canal*, is an antero-posterior slit, the lateral walls resting on each other (Fig. 658). In pathological cases the calibre may be so distended as to occupy the whole pelvis.

The *direction* of the rectum, starting usually from the left of the base of the sacrum, is obliquely downward, backward, and to the right. When it comes to the level of the third sacral vertebra it has reached the middle line. It now passes that line a little and runs along the right lateral part of the fourth sacral vertebra. It again returns to the middle line at about the sacro-coccygeal junction and passes downward and forward, and may cross it a second time till it reaches the level of a transverse line drawn between the anterior parts of the ischial tuberosities. This point is also opposite the apex of the prostate gland (Fig. 657). This point is not opposite the lower end of the coccyx, as often stated, but fully one inch below that.

Sappey thus describes two *lateral curves*, and, with two antero-posterior curves, makes four altogether. The first turn of the rectum from left to right he does not consider a curve. The lateral curves are of little importance, and run into each other. The first is the more pronounced, and corresponds to the junction of the third and fourth pieces of the sacrum, with its concavity to the left. The second corresponds to the sacro-coccygeal junction, with its concavity to the right. They are best seen with an empty rectum, and are almost effaced when it is distended.

The antero-posterior curves are more pronounced and independent of the degrees of dilatation. The first or *sacral curve* is due to the conformation of the sacro-coccygeal column. It has its concavity forward, its convexity being most marked at the junction of the third and fourth sacral vertebrae. The second or *perineal curve* has its convexity forward, corresponding to the apex of the prostate gland in the male and posterior wall of the vagina in the female. Its concavity looks downward and backward. The sacral curve represents the arc of a circle. The last one is angular.

According to its direction, then, the rectum is divided into three parts—a *superior portion*, passing obliquely downward and backward; a *middle portion* passing obliquely downward and forward; an *inferior or anal portion*, passing obliquely downward and backward. They are not of equal lengths; that of the first is 8 to 9 cm.; second, 10 to 11 cm.; third, 2 to 3 cm. in the male, 1.5 to 2 cm. in the female. According to Quain, in order, the first part is five or four inches; second, three or four inches; anal canal, one-half to one inch. In the infant the rectum is straighter, less flexuous, and relatively larger than in the adult. In the female it is said to be larger and straighter than in the male.

The *first*, or *superior*, portion includes about half the length of the tube, and extends obliquely from the pelvic brim, opposite either the left sacro-iliac articulation or the sacro-vertebral angle or the right side of the base of the sacrum, to the body of the third sacral vertebra. It is almost completely surrounded by peritoneum, which is connected to the anterior surface of the sacrum by the
double fold called mesorectum. This is continued above with the sigmoid mesocolon, is triangular, and ends below in an apex at the third sacral vertebra. Some convolutions of the ileum, or a loop of the sigmoid flexure, usually lie in front of this part of the rectum. They separate it from the bladder in the male and posterior surface of the uterus in the female when the rectum is empty. If distended, one of these organs, according to sex, rests on its anterior surface, the intestine being pushed up. Posteriorly is the mesorectum, left Pyriformis muscle, left sacral plexus of nerves, branches of left internal iliac vessels, left portion of anterior surface of two and a half sacral vertebrae. To the left side are the left ureter and left internal iliac vessels. If this part of the rectum come down in the middle line or from the right, these relations will differ.

The middle or second part of the rectum is three or four inches long, and extends from the middle of the third sacral vertebra to a point opposite the apex of the prostate gland. Here the course of the rectum changes to a posterior one, and that is one inch below the tip of the coccyx. It is only partially covered by peritoneum. It has no mesorectum and its posterior surface has no peritoneal covering. At first it is covered anteriorly and laterally, but gradually the peritoneum leaves the sides, and finally, about one inch above the prostate or at the length of an index finger above the anus, never more than 8 cm., it is reflected from the anterior surface of the rectum to the bladder or to the upper fifth of the posterior wall of the vagina, making the pouches as above noted. Distention of bladder or rectum would diminish the depth of these pouches. This part of the rectum is in relation anteriorly in the male with the recto-vesical pouch, with the triangular portion of the base of the bladder, the vesiculæ seminales and vasa deferentia, and beyond them with the under surface of the prostate. In the female it is related anteriorly to the posterior wall of the vagina, with which it is adherent, with the recto-vaginal and recto-uterine pouches and small intestines therein.

The posterior wall lies upon the lower part of the sacrum, middle sacral artery, origin of Pyriformis muscles, coccyx and ano-coccygeal body, and Coccygei muscles. The ano-coccygeal body is a dense mass of muscular-fibrous tissue situated between the tip of the coccyx and anus.

The lower portion or anal canal is about one inch long when the rectum is empty; it is shorter when the rectum is distended. It turns downward and backward at the lower part of the prostate gland and ends at the anal orifice. It has no peritoneal covering. It is invested by the sphincter muscles and supported by the Levatores ani. Behind it is in relation to the ano-coccygeal body and Coccygei muscles; on the sides to the fat of the ischio-rectal fossæ and the Levatores ani muscles.

Anteriorly in the male is the bulb of the urethra and its membranous portion; in the female it is separated from the lower end of the vagina by the perineal body.

The skin about the anus is provided with a ring of sweat-glands called circum-anal glands. The skin is also thrown into minute corrugations by means of little dermal muscles, the Corrugator cutis ani. The anal orifice is not situated alike in the sexes; it is farther forward in the female, and less concealed between the ischial tuberosities. It is 3 cm. in front of the coccyx or just at the bi-ischial line, a little elongated, and the skin is destitute of hair. In the male it is 2.5 cm. in front of the coccyx just behind the bi-ischial line and deeply placed. The skin is covered by hair more or less abundantly, and the orifice is circular and presents little skin folds vertically arranged like rays toward a centre. Between these, where they continue into the mucous membrane, linear excoriations may occur—fissure of the anus.

Structure of the Rectum.

Four coats are again met, but the muscular and mucous ones differ from those yet seen. The walls are 3 to 4 mm. thick, while those of the colon are 1 to 1.5 mm.

The peritoneal coat surrounds the first portion only and forms a mesorectum.
In the second portion it covers the upper part of the anterior surface, a part of the sides, and none of the posterior surface. The lower part is devoid of serous covering. The peritoneum of the upper part of the rectum is thrown into a few pouches, the appendices epiplóica. In women, where the cul-de-sac is lower than in men, the peritoneum covers the whole of the anterior part of the middle portion.

The muscular coat is thick; the three bands of the colon do not spread out and form the uniform layer as described. The anterior band descends along the middle portion of the rectum and continues to the anus. The external band joins the anterior near the end of the sigmoid flexure and runs with it over the first part of the rectum. The internal band is most marked along the middle portion of the rectum and runs posteriorly to the anus. The three bands of the cæcum and colon are reduced to two on the rectum, an anterior and a posterior one. In proportion as they descend they get larger. The endings of these fibres are various: into pelvic fascia, anterior surface of coccyx, and deep surface of skin, just outside the anus. Tendencies to saculation are described, as the longitudinal fibres are rather short. The longitudinal layer is more or less complete between the two bands.

The circular fibres are well developed and especially thick between the saculations. Below, in the anal portion, they become much augmented as the Internal sphincter. This muscle is 3 cm. high, and 3 to 4 mm. thick; below it is precisely limited by the circular line, "white line," which marks the mucous membrane from the skin. It surrounds the whole length of the anal canal and ends very abruptly above in the thinner circular fibres. All these fibres are unstriated.

Posteriorly two Recto-coccygei muscles pass from the second or third vertebra of the coccyx to the posterior part of the anal canal.

The other muscles directly connected are the External sphincter, which descends a little lower than the Internal and surrounds the anal orifice (Fig. 658), and the Levator ani giving support on the sides. These have been described.

The mucous membrane of the rectum is thicker and more vascular than that of the colon, and, moving quite freely on the muscular coat, makes a kind of independent tube. When contracted it shows many folds of no special direction, most of which can be obliterated; some, however, are more permanent, and are called valves of the rectum, or of Houston, or plica recti. Usually three are present, sometimes two or four. One of these, the largest and usually constant, is situated on the right side of the rectum, about at the point where the perito-
neum is reflected upon the bladder, i.e. 6 to 8 cm. above the anal orifice. It is historical, and has been described by Nélaton and Velpeau as sphincter superior; as Houston's "most frequent" valve; as Hyrtl's sphincter tertius; and Kohlransch's plica transversalis. This extends from the right to the anterior wall of the rectum, and cannot be obliterated, as it does not contain longitudinal muscular fibres. It projects 15 mm. into the lumen of the gut and extends around one-half or two-thirds of its inner circumference (Fig. 650). There are generally two other folds on the left side, one about one inch above and the other one inch below, this one of the right side. These two contain all the coats of the wall and may be obliterated by distention. Note the tendency of the three to the formation of a spiral valve. They may all be called valves or folds of Houston. The dilatation between the lowest valve and the anal canal is the rectal ampulla. The presence of these valves may cause difficulty in the passage of bougies or in digital examinations. In function they seem to assist the sphincters and act as shelves in supporting the fecal masses.

In the anal canal the mucous membrane is thrown into three to eight longitudinal folds containing muscular fibres, probably of the muscularis mucosae; they are called columnae ani or columns of Morgagni. They commence just above the anal orifice and extend 7 to 14 mm. up the anal canal, rising 1 to 2 mm. above the level of the mucous membrane. Stretched between these columns at their inferior extremities are semilunar valves or folds made of mucous membrane with concavities turned upward. They are unequal in length, varying inversely with the number of columns.

Behind each valve and between any two contiguous columns is a little concavity or sinus with mouth directed upward. Thus, there are columns, valves, and sinuses of Morgagni (Fig. 660).

---

The characteristic cells of the mucous membrane are cylindrical epithelium. The glands present are those of Lieberkuhn and the solitary lymph-follicles. Inferiorly on the anal canal there is a narrow zone of mucous membrane destined of glands.

**Vessels and Nerves of the Rectum.**—The arteries spring from five or six sources, three of which are named hemorrhoidal: the superior hemorrhoidal from the inferior mesenteric artery; the middle hemorrhoidal from the internal iliac; and the inferior hemorrhoidal from the internal pudic. The saera media and sciatic arteries also send unnamed branches to the rectum, and in the female the vaginal artery does the same. These arteries coming from above form loops on either side of the rectum with convexities pointing downward. These are three or four inches above the anus; from these loops several branches rise, and pass longitudinally downward, pierce the muscular coats and enter the submucosa, and Anastomose freely. In the anal canal they are longitudinal in folds of mucous membrane, and reach to the anal orifice.

The veins return the blood in a similar way, starting by dilatations below and making a plexus higher up under the mucous membrane. Most of this blood is returned by the superior hemorrhoidal vein to the inferior mesenteric vein and portal system. The rest of it reaches the systemic circulation and vena cava inferior. The rectum furnishes an anastomosis between these two systems. It is very strange that the anatomical text-books apply the term hemorrhoidal to all vessels.
connected with the rectum. Of course those vessels supply haemorrhoids when the latter are present, but the implication is, they are always present. The term rectal would seem to be correct and the one intended.

The lymphatics, from mucous and from muscular coats, enter glands anterior to the sacrum. Those near the anus enter inguinal glands.

The nerves are from the sacral plexus (cerebro-spinal), and from the inferior mesenteric and hypogastric plexuses (sympathetic).

In animals the longitudinal muscular fibres have a motor supply from the sacral nerves.

**Relations of the Rectum in Detail.**

**First Portion.**

**Anteriorly:**
- Small intestines;
- Sigmoid flexure;
- Posterior surface of bladder in *male*;
- Posterior surface of uterus in *female*.

**Posteriorly:**
- Mesorectum;
- Left Pyriformis muscle;
- Left sacral plexus;
- Left internal iliac vessels;
- Anterior surface of first two and a half sacral vertebrae.

**Externally:**
- Left ureter;
- Left internal iliac vessels.

**Second Portion.**

**Anteriorly:**
(Male) Recto-vesical pouch;
- Small intestines;
- Triangular portion of bladder;
- Vesiculae seminales;
- Vasa deferentia;
- Under surface of prostate gland.

(Female) Posterior wall of vagina;
- Recto-vaginal pouch;
- Recto-uterine pouch;
- Small intestines.

**Posteriorly:**
- Lower part of sacrum;
- Coccyx;
- Ano-coccygeal body;
- Middle sacral vessels;
- Origin of Pyriformis muscles.

**Third Portion, or Anal Canal.**

**Anteriorly:**
(Male) Bulb of urethra;
- Membranous urethra.

(Female) Perineal body.

**Posteriorly:**
- Ano-coccygeal body;
- Coccygei muscles.
Laterally:

Fat of ischio-rectal fossae;
Levatores ani muscles.

The other ways of describing the rectum (page 1038) only affect its method of subdivision.

Treves describes the two lower parts of the rectum and includes the first in the sigmoid flexure. This is doubtless an improvement on the old method. He says:1 "The segments of the gut termed the sigmoid flexure and first part of the rectum form together a single loop which cannot be divided into parts. This loop begins where the descending colon ends, and ends at the spot where the mesorectum ceases opposite the third piece of the sacrum. This loop when unfolded describes a figure that may be compared to the capital omega" (Fig. 661).

"The average length of this adult omega loop is seventeen and a half inches, varying from six to twenty-seven. Its normal position is not in the left iliac fossa, but in the pelvis. Its most usual arrangement is this: the descending colon ends just at the outer border of the Psoas. The gut crosses the muscle at right angles and descends vertically along the left pelvic wall, and may at once reach the pelvic floor. It then passes more or less horizontally and transversely across the pelvis from left to right and commonly comes into contact with the right pelvic wall. Here it is bent upon itself, and passing once more toward the left reaches the middle line and descends to the anus" (Fig. 662).

The line of attachment of the mesocolon that fastens the omega loop is as follows (Fig. 661): "It crosses the Psoas at a right angle, and then takes a slight curve upward so as to pass over the iliac vessels about at their bifurcation. The curve ends at the point X, which is most frequently at the bifurcation of the vessels. From here the line of attachment proceeds vertically down to terminate at N. Its course is to the left of the middle line, while its ending will be upon that line. At the point X the mesocolon is folded a little, and here there arises that part of the membrane which goes to the summit of the loop Y. Here the mesocolon attains its greatest length, and at this spot the sigmoid artery enters. The average length of the mesocolon is over the Psoas one and a half inches; at the point X three and a half inches; on the sacrum one and three-fourths inches. The distance between the ends of the loop M and N is three inches."

1 Hunterian Lectures, 1885: "The Anatomy of the Intestinal Canal and Peritoneum in Man."
Surface Form.—The coils of the small intestine occupy the front of the abdomen below the transverse colon, and are covered more or less completely by the great omentum. For the most part, the coils of the jejunum occupy the left side of the abdominal cavity—i. e. the left lumbar and inguinal regions and the left half of the umbilical region—whilst the coils of the ileum are situated to the right, in the right lumbar and inguinal regions, in the right half of the umbilical region, and also the hypochondriac. The caecum is situated in the right inguinal region. Its position varies slightly, but in most cases is about the middle of a line drawn from the anterior superior spine process of the ilium to the symphysis pubis, which is the middle of its lower border. It is comparatively superficial. From it the ascending colon passes upward through the right lumbar and hypochondriac regions, and becomes more deeply situated as it ascends to the hepatic flexure, which is deeply placed under cover of the liver. The transverse colon crosses the belly transversely on the confines of the umbilical and epigastric regions, its lower border being on a level slightly above the umbilicus, its upper border just below the greater curvature of the stomach. The splenic flexure of the colon is situated behind the stomach in the left hypochondrium, and is on a higher level than the hepatic flexure. The descending colon is deeply seated, passing down through the left hypochondriac and lumbar regions to the sigmoid flexure, which is situated in the left inguinal regions, and which can be felt in thin persons, with relaxed abdominal walls, rolling under the fingers when empty, and when distended forming a distinct tumor.

Surgical Anatomy.—The small intestines are much exposed to injury, but, in consequence of their elasticity and the ease with which one fold glides over another, they are not so frequently ruptured as would otherwise be the case. Any part of the small intestine may be ruptured, but probably the most common situation is the transverse duodenum, on account of its being more fixed than other portions of the bowel, and because it is situated in front of the bodies of the vertebrae, so that if this portion of the abdomen is struck by a sharp blow, as from the kick of a horse, it is unable to glide out of the way, but is compressed against the bone and so lacerated. Wounds of the intestine sometimes occur. If the wound is a small puncture, under, in is said, three lines in length, no extravasation of the contents of the bowel takes place, and the injury may be safely punctured with a fine capillary trocar, in cases of excessive distension of the intestine with gas, without fear of extravasation. A longitudinal wound gapes more than a transverse, owing to the greater amount of circular muscular fibres. The small intestine, and most frequently the ileum, may become strangulated by internal bands, or through apertures, normal or abnormal. The bands may be formed in several different ways: they may be old peritoneal adhesions from previous attacks of peritonitis; or an adherent omentum from the same cause; or the band may be formed by Meckel's diverticulum, which has contracted adhesions at its distal extremity; or the band may be the result of the abnormal attachment of some normal structure, as the adhesion of two appendixes epiploicae, or an adherent veriform appendix or Fallopian tube. Intussusception or invagination of the small intestine may take place in any part of the jejunum and ileum, but the most frequent situation is in the ileocecal valve, the valve forming the apex of the entering tube. This form may attain great size, and it is not uncommon in these cases to find the valve projecting from the anus. Stricture, the impaction of foreign bodies, and twisting of the gut (volvulus) may lead to intestinal obstruction.

Foreign bodies and small hardened masses of fecal matter are very liable to become lodged in the veriform appendix. Here they set up inflammation, often cause perforation of the appendix and formation of abscess in the loose connective tissue around. This may require operative interference, and in some cases of recurrent attacks of appendicitis this little diverticulum of the bowel has been removed. In external hernia the ileum is the portion of bowel most frequently herniated. When a part of the large intestine is involved, it is usually the caecum, and this may occur even on the left side. In some few cases the veriform appendix has been the part implicated in cases of strangulated hernia, and has given rise to serious symptoms of obstruction. Occasionally ulceration of the duodenal glands may occur in cases of burns, but is not a very common complication. The ulcer may perforate one of the large duodenal vessels, and may cause death from hemorrhage, or it may perforate the coats of the intestine and produce fatal acute peritonitis. The diameter of the large intestine gradually diminishes from the caecum, which has the greatest diameter of any part of the bowel, to the point of junction of the sigmoid flexure with the rectum, at or a little below which point stricture most commonly occurs and diminishes in frequency as one proceeds upward to the caecum. When distended by some obstruction low down, the outline of the large intestine can be defined through nearly the whole of its course—all, in fact, except the hepatic and splenic flexures, which are more deeply placed; the distension is most obvious in the two flanks and on the front of the abdomen just above the umbilicus. The caecum, however, is that portion of the bowel which is, of all, most distended. It sometimes assumes enormous dimensions, and has been known to be perforated from the pressure, causing fatal peritonitis. The hepatic flexure and the right extremity of the transverse colon is in close relationship with the liver, and absees of this viscus sometimes bursts into the gut in this situation. The gall-bladder may become adherent to the colon, and gall-stones may find their way through into the gut, where they may become impacted or may be discharged per anum. The mobility of the sigmoid flexure renders it more liable to become the seat of a volvulus or twist than any other part of the intestine. It generally occurs in patients who have been the subjects of habitual constipation, and in whom, therefore, the meso-sigmoid flexure is elongated. The gut at this part being loaded with feces, from its weight falls over the gut below, and so gives rise to the twist.
The surgical anatomy of the rectum is of considerable importance. There may be congenital malformation due to arrest or imperfect development. Thus, there may be no inflow of the epiblast (see page 134), and consequently a complete absence of the anus; or the hind-gut may be imperfectly developed, and there may be an absence of the rectum, though the anus is developed; or the inflow of the epiblast may not communicate with the termination of the hind-gut from want of solution of continuity in the septum which in early fetal life exists between the two. The mucous membrane is thick and but loosely connected to the muscular coat beneath, and thus favors prolapse, especially in children. The vessels of the rectum are arranged, as mentioned above, longitudinally, and are contained in the loose cellular tissue between the mucous and muscular coats, and receive no support from surrounding tissues, and this favors varicosity. Moreover, the blood from these vessels is returned into the general circulation through two distinct channels—part through the systemic system and part through the portal system—so that they may be said to be placed between the portal and systemic circulations, and thus predisposed to congestion and consequent dilatation. In addition to this, there are no valves in the superior hemorrhoidal veins, and the vessels of the rectum are placed in a dependent position, and are liable to be pressed upon and obstructed by hardened feces. The anatomical arrangement, therefore, of the hemorrhoidal vessels explains the great tendency to the occurrence of piles. Again, the presence of the Sphincter ani is of surgical importance, since it is the constant contraction of this muscle which prevents an ischio-rectal abscess from healing and causes it to become a fistula. Also, the reflex contraction of this muscle is the cause of the severe pain complained of in fissure of the anus. The relations of the peritoneum to the rectum are of importance in connection with the operation of removal of the lower end of the rectum for malignant disease. This membrane gradually leaves the rectum as it descends into the pelvis; first leaving its posterior surface, then the sides, and then the anterior surface to become reflected in the male on to the posterior wall of the bladder, forming the recto-vesical pouch, and in the female on to the posterior wall of the vagina, forming Douglas's pouch. The recto-vesical pouch of peritoneum extends to within three and a half or four inches from the anus, so that it is not safe to remove more than three inches of the entire circumference of the bowel for fear of the risk of opening the peritoneum. When, however, the disease is confined to the posterior surface of the rectum, or extends farther in this direction, a greater amount of the posterior wall of the gut may be removed, as the peritoneum does not extend on this surface to a lower level than five inches from the margin of the anus. The recto-vaginal or Douglas's pouch in the female extends somewhat lower than the recto-vesical pouch of the male, and therefore it is necessary to remove a less length of the tube in this sex.\(^1\) Upon introducing the finger into the rectum the membranous portion of the urethra can be felt, if an instrument has been introduced into the bladder, exactly in the middle line; behind this the prostate gland can be recognized by its shape and hardness and any enlargement detected; behind the prostate the fluctuating wall of the bladder when full can be felt, and if thought desirable it can be tapped in this situation; on either side and behind the prostate the vesiculce seminales can be readily felt, especially if enlarged by tubercular disease. Behind, the coccyx is to be felt, and on the mucous membrane one or two of Houston's folds. The ischio-rectal fossae can be explored on either side of this finger, and, if present, the presence of the osseous plates of the coccyx. Finally, it will be noted that the finger is firmly gripped by the sphincter for about an inch beyond the lower edge. By gradual dilatation of the sphincter the whole hand can be introduced into the rectum so as to reach the descending colon. This method of exploration is rarely, however, required for diagnostic purposes.

The colon frequently requires opening in cases of intestinal obstruction, the descending colon being usually the portion of bowel selected for this operation. The operation of colotomy may be performed either without opening the peritoneum by an incision in the loin (lumbar colotomy), or by an opening through the peritoneum (inguinal colotomy). Lumbar colotomy is performed by placing the patient on the side opposite to the one to be operated on, with a firm pillow under the loin. A line is then drawn from the anterior superior to the posterior superior spine of the ilium, and the mid-point of this line (Heath) or half an inch behind the mid-point (Allingham) is taken, and a line drawn vertically upward from it to the last rib. This line represents, with sufficient correctness, the position of the normal colon. An oblique incision four inches in length is now made midway between the last rib and the crest of the ilium, so that its centre bisects the vertical line, and the following parts successively divided: (1) The skin, superficial fascia, with cutaneous vessels and nerves and deep fascia. (2) The posterior fibres of the External oblique and anterior fibres of the Latissimus dorsi. (3) The Internal oblique. (4) The lumbar fascia and the external border of the Quadratus lumborum. The edges of the wound are now to be held apart with retractors, and the transversalis fascia will be exposed. This is to be opened with care, commencing at the posterior angle of the incision. If the bowel is distended, it will bulge into the wound, and no difficulty will be found in dealing with it. If, however, the gut is empty, this bulging will not take place, and the colon will have to be sought for. The guides to it are the lower end of the kidney, which will be plainly felt, and the outer edge of the Quadratus lumborum. The bowel having been found, is to be drawn well up into the wound, and it may be opened at once and the margins of the openings stitched to the skin at the edge of the wound; or, if the case is not an urgent one, it may be retained in this position by two hairpin pins passed through the muscular coat, the rest of the wound closed, and the

\(^1\) Allingham says one inch less in the female.
bowed opened in three or four days, when adhesion of the bowel to the edges of the wound has

taken place.

Inguinal colotomy is preferred by many surgeons in those cases where there is no urgent
obstruction, and where, therefore, there is no necessity to open the bowel at once. The main
reason for preferring this operation is that a spur-shaped process of the meso-colon can be formed
which prevents any faecal matter finding its way past the artificial anus and becoming lodged on
the diseased structures below. The sigmoid flexure being almost entirely surrounded by peritoneum, a coi can be drawn out of the wound and the greater part of its calibre removed, leaving
the remainder attached to the meso-colon, which forms a spur, much the same as in an
artificial anus caused by sloughing of the gut after a strangulated hernia, and this prevents any
faecal matter finding its way from the gut above the opening into that below. The operation is
performed by making an incision two or three inches in length from a point one inch internal to
the anterior superior spinous process of the ilium, parallel to Poupart’s ligament. The various
layers of abdominal muscles are cut through, and the peritoneum opened and sewn to the
external skin. The sigmoid flexure is now sought for, and pulled out of the wound and fixed by
passing a needle threaded with carbolized silk through the meso-colon close to the gut and then
through the abdominal wall. The intestine is now sewn to the skin all round, the suture passing
only through the serous and muscular coats. The wound is dressed, and on the second to the
fourth day, according to the requirements of the case, the protruded coil of intestine is opened
and removed with scissors.

THE LIVER.

The Liver (Hepar) is a gland intended for the secretion of sugar and bile, remarkable for its size, equalling that of all the other glands put together, and for its connections with the system of the portal vein which ramifies in its sub-
stance. It may be described under two heads: (1) External conformation: (2) Structure or Histology. First we shall study its sit-
uation, its volume, its weight, its consistence and color, its form, its relations, and its means of fixation. This
organ fills almost all the right hypochondrium, a great part of the epigastrium, and advances into the left hypoch-
drium as far as the mammary line in the neighbor-
hood of the spleen. It is situated, consequently, below
the diaphragm, which separates it from the lungs and
heart: above the stomach, duodenum, transverse colon,
and small intestines, which form a sort of pillow: and
behind are the right false ribs, which protect it. In an
embryo of three weeks this organ fills the greater part
of the abdomen (Fig. 663). During the first half of
intra-uterine life its anterior border is below the umbil-
icus. In a child of six or eight years it gets behind the
free border of the right false ribs. In the adult its
average transverse dimension is 28 cm. (eleven inches),
its antero-posterior dimension is 20 cm. (eight inches),
and vertical dimension is 6 cm. (two and a half inches)
(Sappey). Quain’s figures are—greatest vertical diam-
eter on the right lobe, five to seven inches, greatest transverse is one or two
inches more; its greatest antero-posterior diameter is above the right kidney,
four to six inches, and in front of the vertebral column is two and a half to four
inches. All this varies with the individual, the amount of blood contained, and
the state of digestion and pathological state.

Its volume is 90 to 100 cubic inches.

The absolute weight of the liver is proportional to its volume and amount of
blood contained. The average is in bloodless livers 1.451 kg.; in physiological
livers containing blood, 1.937 kg., or about one-thirty-second of the body-weight.
At birth it is one-eighteenth of the body-weight. This is 50 or 60 ounces avoid-
dupois in the male, a little heavier than the brain, and 40 to 50 ounces in the
female. Its specific gravity is 1.046. The consistence of the liver is soft, but
harder than that of other glands. It has a certain friability. Its tissue is more
easily crushed than depressed.

The physiological color is a dark, reddish brown. In the young it takes on a
brighter tone, due to the milk diet, and in later years may assume other shades, due to pathological changes. After death it may be red-brown at one place, yellow at another, with all variations; sometimes the colors occur in wavy lines. This means only unequal repletion of the vessels. The liver possesses no shape peculiar to itself. Like the lachrymal, or parotid gland, or pancreas, it is moulded to neighboring organs. Its general contour, however, is wedge-shaped, with the base to the right. Many compare it to the upper section of an ovoid cut by a plane passing from below upward to the left (Fig. 664). The right end is thick and the left end thin.

The various surfaces ascribed to the liver are from two to five, resulting from the method of observation. A pathological, bloodless, decayed liver placed on the dissecting table as usually seen by the student, will always have two surfaces. It does not follow that that liver shows anything of its normal appearance during life. The inferior vena cava of this liver is horizontal on its inferior surface, yet we know that vessel runs vertically along the spinal column. A liver removed from the body and injected does not give the correct form. Hardening in situ by chromic acid or formalin injections leaves the shape of the viscera as in life. The liver treated thus shows three surfaces, a superior, inferior, and posterior; an anterior border, a right, and a left extremity. That which was formerly called the posterior blunt margin is now seen to be a posterior surface. Symington regards the shape of the liver as that of a right-angled triangular prism, and describes five surfaces, right basal or lateral, anterior, superior, posterior, and inferior.

The convex, upper, smooth surface of the liver is subdivided by a sagittal fold of peritoneum drawn down from the diaphragm, called the suspensory, broad, or falciform ligament. To its right is a larger, broader convex lobe, and on the left a smaller, more slender, flatter lobe (Fig. 665). This broad ligament corresponds on the under concave surface of the liver to the left longitudinal fissure
(Fig. 666) running from before backward. This fissure also divides the under surface into a right and left lobe. The left lobe is variable, and usually constitutes one-sixth of the gland. Three more lobes are seen on the inferior and posterior surfaces of the right one, from before backward, the quadrate, the caudate, or tuberulum caudatum, and Spigelian lobes.

**Surfaces.**—The superior or phrenic surface is convex, directed upward and forward and covered by peritoneum except for the linear space between the layers of the broad ligament. It includes the upper surface of the right and left lobes, the former being convex and the latter more flat. Between and upon the two is a shallow depression or flattening corresponding to the central tendon of the diaphragm and to the heart.

This separation of lobes continues below in the attachment of the falciform ligament and incisura umbilicalis, umbilical or interlobular notch. To the right of the notch is a concavity intruding upon this surface, occupied by the fundus of the gall-bladder, the incisura vesicalis. This whole surface is in relation to the under surface of the diaphragm, and below to a small extent with the anterior abdominal wall.

The inferior or visceral surface is uneven, concave, and directed backward, downward, and to the left. It is in relation with the stomach, duodenum, the hepatic flexure of the colon, the right kidney, and suprarenal capsule. This surface, as we have seen, is divided into a right and left portion by the left longitudinal fissure. It is invested by peritoneum of the greater sac, except where the gall-bladder is adherent to it, and at the transverse fissure or hilus where the two layers of lesser omentum are attached.

The under surface of the left lobe is moulded over the cardia of the stomach. Near the centre and right part of this surface a result of moulding is seen in a large rounded tubercle, the tuber omentale, which fits into the concavity of the lesser curvature of the stomach. The whole tubercle is made from the under surface of the left lobe and the lower left corner of the Spigelian. It is in front of
the anterior layer of the lesser omentum. Here it meets another tuber omentale coming upward and forward from the pancreas.

The under surface of the right lobe has a middle piece cut off from it by the fossa for the gall-bladder, fossa vesicalis. This forms a quadrat or anterior lobe which is just above the pyloric end of the stomach and the superior curvature of the duodenum. To the right of the quadrat lobe and gall-bladder, the under surface of the right lobe shows two marked concavities separated by a ridge. The anterior concavity is made by the hepatic flexure of the colon, impressio colica; we have seen how this ascends in front of the right kidney, so posteriorly the next concavity is the impressio renalis.

At the inner border of the renal impression is another for the second part of the duodenum, impressio duodenalis; this lies outside the neck of the gall-bladder and is limited internally by the cystic duct. The superior curve of the duodenum crosses the neck of the gall-bladder or even the transverse fissure, and comes under the caudate lobe. The pyloric end of the stomach touches the quadrat lobe, starting from its anterior border. Sometimes there is an impressio pylorica.

The impression for the right suprarenal capsule is farther back than the impressio renalis and close to the inferior vena cava. Its basal part rests upon the under surface of the liver at the posterior tip of the renal impression. This part of the impression is covered by peritoneum. Its apex extends up on the posterior surface of the liver just to the right of the vena cava. This part of its impression is not covered by peritoneum. So the impressio suprarenalis has two parts, one covered with peritoneum on the inferior surface of the liver and one uncovered by peritoneum on the posterior surface.

Just anterior to the vena cava is a narrow area of liver tissue connecting the right lower corner of the Spigelian lobe to the under surface of the right lobe. It is the tuberculum caudatum, not always big enough to be called the caudate lobe (cauda, tail). This lies above the foramen of Winslow.

The posterior surface is rounded and broad behind the right lobe, but narrow on the left. To the right is not covered by peritoneum for a space about three inches broad and two inches high. This is in direct contact with the diaphragm and posterior abdominal wall, and is marked off from the upper surface by the line of reflection of the peritoneum from the diaphragm to the liver. This part constitutes the anterior layer of the coronary and right lateral ligaments. It is marked off from the under surface of the liver by a similar line of reflected peritoneum from the posterior part of the diaphragm to the liver, which here forms the inferior or posterior layer of the coronary and right lateral ligaments. A small peritoneal area exists on the posterior surface to the right of the rough area.

At the lower and inner part of this rough surface is the non-peritoneal part of the impressio suprarena
dalis. The inner border of the surface projects over the vena cava, and not rarely encloses it in a canal of liver tissue. The centre of the posterior surface is deeply grooved for the vertebral column and aorta.

The lobe so grooved is the Spigelian; it rests against the tenth and eleventh dorsal vertebrae, the aorta and crura of the diaphragm, but upon the right crus more than the left. The right crus grooves it from the right lower corner to the left upper corner; here also is the oesophagus. The end of the thoracic aorta lies behind the left lower corner separated by the diaphragm. To its right is the fossa or canal for the inferior vena cava; to its left is the furrow for the obliterated remains of the ductus venosus Arantii. In fetal life this duct establishes communication between the vena umbilicalis and vena cava inferior. Still farther to the left of this is a groove for the oesophagus and beginning of the cardia.

The free surface of the Spigelian lobe looks backward, is nearly vertical, and is concave from side to side. Its superior border slopes toward the upper surface of the liver, but is separated from it by a double layer of peritoneum. Below, its inferior margin shows a slight notch separating a right part, which joins the caudate tubercle or lobe, and a left part called papillary tubercle, tuber papillare.
This is seen as the most prominent part of the lobe when the lesser omentum is divided in front. This lobe is the only part of the liver covered by the peritoneum of the lesser sac. The finger goes under the caudate lobe, through the foramen of Winslow, and passes up behind the Spigelian lobe. Above, it is limited by the posterior layer of the coronary ligament; to the right it is obstructed by the layer of the lesser sac attached to the caval fossa; and to the left the finger cannot pass over to the stomach by reason of the double layer attached to the fissure of the ductus venosus. All of the right lobe, except its posterior part, and all of the left and quadrate lobes are covered by peritoneum of the greater sac. That on the caudate is divided between the two sacs.

Finally, to the extreme left of the posterior surface we have the thin posterior edge of the left lobe sharply under-cut by the inferior surface. His regards the tuber omentale as on the posterior surface.

The anterior border is thin and sharp and marked opposite the attachment of the falciform ligament by the umbilical notch (incisura umbilicalis), and opposite the cartilage of the ninth rib by a second notch for the fundus of the gall-bladder (incisura vesicalis). In adult males this border usually corresponds with the free margin of the ribs; in women and children it may project below.

The right extremity of the liver is thick and rounded, convex from before backward and usually from above downward. Its upper and anterior angles are rounded. Below it forms an acute margin with the under surface.

The left extremity is thin and flattened from above downward.

The fissures of the liver closely follow the lines of the letter H (Meckel), supposing them projected upon a flat surface (Fig. 667). They are five in number, situated upon the inferior and posterior surfaces of the liver, often called fossae instead of fissures. The transverse fissure, or porta hepatis (gate of the liver), is the most important, because the great vessels and nerves enter here and the hepatic ducts and lymphatics pass out. It is a short, deep fissure, 5 cm. long (two inches) and 12 to 15 mm. wide (one-half inch); it is on the under surface of the right lobe, passing transversely a little nearer the posterior surface than the anterior margin and nearer than the left extremity than the right. It separates the quadrate lobe in front from the caudate and Spigelian lobes behind, and joins the two longitudinal fissures at nearly right angles. The two vertical arms of the H are represented by the two longitudinal fissures, right and left.

The left longitudinal, or sagittal, fissure (fossa longitudinalis sinistra) separates the right from the left lobe, and is divided into an anterior and posterior part by its junction with the transverse fissure. The anterior part is the umbilical fissure, which contains the umbilical vein in the foetus and its remains in the adult, which is then called the round ligament (Lig. teres). It lies between the quadrate and left lobes of the liver. This fissure, and the one for the ductus venosus, are often bridged over by liver tissue (pons hepatis), converting a fissure wholly or partially into a canal.

The posterior part of the left longitudinal fissure is not so marked as the anterior part; it passes between the lobe of Spigelius and the left lobe, and is called the fissure of the ductus venosus. In the foetus it lodges a vein, but in the adult this vein becomes a slender cord, lig. venosum.

The right longitudinal fissure (fossa longitudinalis dextra) runs parallel to the left one, and has an anterior and posterior part. It meets one interruption just behind the transverse fissure, where the caudate lobe connects the Spigelian and
right lobe. The *posterior part* is the fossa of the vena cava, which separates the Spigelian from the right lobe, and is separated from the transverse fissure by the caudate lobe. It is a deep fossa, sometimes a canal; at its upper part the hepatic veins enter the floor of the fossa and end in the vena cava. The *anterior part* of this longitudinal fissure is the fossa for the gall-bladder, *fossa vesicalis*. The proposed name is fossa vesicce felleae. It is a shallow, oblong fossa on the under surface of the right lobe, and runs from the incisura vesicalis to near the right end of the transverse fissure.

The *transverse, umbilical, and vesical fissures* are on the under surface of the liver, and the *fissures* for the ductus venosus and vena cava are on the posterior surface.

**Lobes.**

We have seen five lobes, though one, the caudate, is very small. The boundaries between *right* and *left* are, superiorly, the attachment of the falciform ligament; anteriorly, the umbilical incisure; inferiorly, the lig. teres in the umbilical fissure; posteriorly, the lig. venosum in the fissure for the ductus venosus.

The *right lobe* is much larger than the left, and is of quadrate form. Three fissures are on its under and posterior surfaces: the transverse, and those for gall-bladder and vena cava. These separate three more lobes, all belonging to the right one. Three impressions are seen—renal and supraprenal, colic, and duodenal.

The *left lobe* is convex above, but less so than the right, and concave below, where it rests on the stomach. This impression is in front of the groove for the oesophagus, and is separated from the longitudinal fissure by the omental tuberculosis which lies against the lesser omentum and lesser curvature of the stomach.

The *quadrat* or *square lobe* on the under surface of the right is bounded anteriorly by the acute margin of the liver; to the right by the fossa for the gall-bladder; to the left by the umbilical fissure and behind by the transverse fissure. Its length is greater from before backward than from side to side. It may present an *impressio pylorica*.

The *caudate lobe or tubercle* is on the under surface of the right lobe between the fossa for the gall-bladder and that for the vena cava, at the right end of the transverse fissure. It connects the right lobe with the right lower corner of the Spigelian lobe.

The *Spigelian lobe* is on the posterior surface of the right one, looks directly backward, and is wholly included in the atrium bursa omentalis. It reaches below as far as the pancreas and celiac axis. It is bounded above by the coronary ligament; to the right by the fossa for the vena cava; to the left by the fissure for the ductus venosus, and below by the transverse fissure. Its left upper angle is partly grooved for the oesophagus. Its *papillary tubercle* looks directly downward.

The technical names of the parts seen on the three surfaces of the liver are, in order from left to right—

**Superior surface:** Upper surface left lobe, umbilical incisure, attachment of falciform ligament, cardiac impression on both lobes, vesical incisure, upper surface of right lobe (Fig. 665).

**Posterior surface:** Thin margin of left lobe, oesophageal incisure, lig. venosum in fissure for ductus venosus, lobus Spigelli in front of the tenth and eleventh dorsal vertebrae; papillary tubercle; fossa for the vena cava and hepatic veins; non-peritoneal impression for part of the right supraprenal capsule; non-peritoneal surface of right lobe for the diaphragm (Fig. 666).

**Inferior surface:** Gastric impression on the under surface of left lobe; tuber omentale which includes lower left part of Spigelian lobe; umbilical fissure and lig. teres; quadrat lobe with impressio pylorica and duodenalis (first portion); fossa for gall-bladder; remainder of under surface of right lobe; impressio duodenalis (second portion); peritoneal impression for supraprenal capsule; impressio renalis posteriorly, and colica, anteriorly.

There are some *abnormal forms* of the liver. Frequently the left lobe is so
elongated it may reach the spleen or even be hooked around it or inseparably fused with it. The papillary tubercle may be so developed as to form a separate lobule. An accessory lobe may be attached to the left one, united by peritoneum and blood-vessels. Many times the number of lobes are diminished and the form becomes square or spherical. More often the number of lobes increases, separated by short deep clefts called *rima cava*.

Besides congenital changes, others may be acquired by pressure. By excessive lacing in women the superficial part of the liver will become atrophic and the peritoneal coat will become thicker. On the convex surface of the liver a transverse furrow will be established dividing off an anterior portion, especially of the right lobe. This part will be pushed down into the abdominal cavity, and may become almost separated from the rest—the "corset liver." If the liver be more resistant, its surface may show the flat, stripe-like impressions occasioned by the ribs.

**Ligaments and Peritoneal Relations.**—The liver is connected in part by peritoneum to the roof of the abdominal cavity, to the anterior wall, to the stomach, duodenum, right kidney, and hepatic flexure of colon, whereby the following peritoneal folds or ligaments are to be distinguished. With one exception they are peritoneal folds.

The *coronary ligament* connects the posterior surface of the liver to the diaphragm. Its two layers surround the rough triangular surface seen on the posterior part of the right lobe, which is connected directly to the diaphragm by areolar tissue. These layers are reflections from the parietal peritoneum descending from the diaphragm. This ligament has three portions (Fig. 668). The right part is much the bigger and its layers are far apart, enclosing the posterior rough surface of the right lobe. The two layers are derived from the peritoneum of the greater sac. A middle portion is seen above the Spigelian lobe. The two layers are close together; the anterior one belongs to the greater sac, and the posterior one to the lesser. Farther to the left is a third narrow portion continued into the left lateral ligament. Both layers here belong to the greater sac. On either end of the coronary ligament the two layers of peritoneum gradually approach, and finally unite, thus forming the right and left lateral ligaments as prolongations of the coronary. As they enclose a triangular space, they are also called triangular ligaments; the left is the longer, and lies in front of the oesophagus. The right is often imperceptible.

The *suspensory, longitudinal, falciform, or broad* ligament is a part of the old anterior mesentery of the stomach and duodenum. The liver was developed in it, budding out from the duodenum, where its duct is still attached. This is a thin membrane which passes antero-posteriorly above the liver and below it. Above it meets the coronary ligament at right angles. By one of its margins it is connected with the posterior layer of the sheath of the right Rectus abdominis muscle as far as the umbilicus, and above to the under surface of the diaphragm, where it spreads out to the right and left. By its other margin it is attached along the upper surface of the liver, its left layer passing over the left lobe and continuing into the left part of the coronary and left lateral ligament. Its right layer passes over the right lobe and corresponding ligaments. The remaining margin is free and rounded, and passes from the interlobular notch to the transverse fissure of the liver. It contains between its two layers the intra-abdominal part of the umbilical vein of the fetus, now a fibrous cord, the round ligament (lig. hepato-umbilicalis), which is lodged in the umbilical fissure. Also between the two layers run some branches of the epigastric veins anastomosing with the portal system, little twigs of the phrenic arteries, numerous lymphatics, and branches of the phrenic nerve which are destined for the serosa of the liver and for the peritoneum of the anterior abdominal wall. In its natural position the falciform ligament forms a pocket, which, with the diaphragm and abdominal wall, enclose the convex upper part of the left lobe of the liver. This ligament has no function of suspension.

Besides these there are others hardly less marked which we have noted in the study of the peritoneum. The *lesser omentum* (lig. gastro-hepaticum) with its
two layers attached to the anterior and posterior borders of the transverse fissure, descends to the lesser curvature of the stomach, containing between its layers some ascending branches of the left vagus nerve. The posterior layer descends behind the stomach as the anterior wall of the bursa omentalis, and arches behind the cardia into the posterior wall of this bursa. On the right both layers unite, forming a free edge, constituting the anterior margin of the foramen of Winslow.

This edge, whose layers separate below and nearly enclose the whole of the superior curve of the duodenum, constitutes the lig. hepato-duodenale, which contains the portal vein, hepatic artery, common bile-duct, lymphatics and nerves (not hepatic veins).

A part of this ligament passes over the duodenum into the great omentum and reaches the transverse colon. This is the hepato-colic ligament (Fig. 635).

The lig. hepato-renale passes down from the under surface of the right lobe rising near the neck of the gall-bladder and vena cava and behind the foramen of Winslow to the upper part of the right kidney. It possesses a free edge directed forward. Between this and the right lateral ligament of the liver is often a recess, recessus hepato-renalis, into which fits the right end of the inferior and posterior surfaces of the liver. The posterior wall of this recess touches in part the right suprarenal capsule and in part the right kidney. That part of the hepato-duodenal ligament which rises from the gall-bladder is the lig. cystico-duodenale.

The ligaments of the liver are coronary, right and left lateral or triangular, falciform or suspensory, round or lig. hepato-umbilicalis, lesser omentum, which consists of lig. hepato-gastricum and lig. hepato-duodenale, lig. cystico-duodenale, lig. hepato-colicum, and lig. hepato-renale (Figs. 615 and 635).

Peritoneal Lines.—Beginning at the left, we see the space between the two layers of the left lateral ligament (Figs. 668 and 665). The anterior layer belongs wholly to the greater sac. It passes from the left lateral ligament to the left layer of the falciform, forming a part of the coronary. This becomes continuous with the right layer at the umbilicus. The right layer runs along the upper margin of the liver, making the middle part of the coronary ligament, and then goes to the right, forming the rest of the coronary in front of the posterior rough surface on the liver, finally ending in the right lateral ligament. Taking the posterior layer from this point, we shall see it belongs mostly to the greater sac. It first completes the right lateral ligament, then runs behind the rough surface and enters into the impressio renalis, forming the lig. hepato-renale. It then passes under the rough impressio suprarenale in front of the vena cava and behind the tuberculum caudatum to the lobus Spigelii. It ascends on high to the left of the vena cava, surrounds the upper end of the Spigelian lobe, descends on its left side, turns in front of the papillary tubercle, follows the anterior edge of the caudate tubercle, and goes back to the right lobe. It here enters upon the under surface of the

---

**Fig. 668.**—"Peritoneal lines" of the liver. Schematic.
THE LIVER.

1055
gall-bladder and undergoes a more or less sharp bend, and passes to the anterior margin of the transverse fissure, following the posterior edge of the quadrate lobe to the left. It now reaches the tuber omentale, ascends on the left side of the fissure for the ductus venous, and, making nearly a right angle, is prolonged above upon the left lobe. Here it forms the posterior edge of the lateral ligament. All the parts between the lines thus traced are not covered by peritoneum. This all belongs to the peritoneum of the greater sac except that which surrounds the Spigelian lobe; this belongs to the lesser sac or atrium of the omental bursa.

Relations of the Liver.

It lies in both hypochondria and in the epigastrium. It completely fills the right hypochondrium and sometimes enters the right lumbar region. Its entire right lobe lies in the right side of the abdominal cavity; only the left lobe reaches the left half of the body. The left longitudinal fissure and the attachment of the broad ligament, and the interlobar incisure which mark the limits between the right and left lobes, correspond almost always to the median line of the body (Fig. 626). Its convex upper surface fits itself to the concavity of the diaphragm, in which it glides as if in a joint-socket. The upper limit of the liver corresponds to that of the diaphragm. On the right side in the mammary line it is at the middle of the fourth intercostal space; on the left in the mammary line it is at the upper border of the fifth space. It does not usually go beyond this line. Above the right lobe rests the concave base of the right lung. In percussing the side of the chest downward three regions are noted—first, one of relative liver dulness, where it is covered by the lung; second, the region of costo-phrenic sinus, where diaphragm and not lung intervenes; third, absolute liver dulness below the diaphragm. A stab here could wound at the same time the pleura, right lung, diaphragm, peritoneum, and convex surface of the liver. Above the right and left lobes are the heart and then the lung. The convex surface of the liver is covered on the right side by the greater part of the lower six or seven ribs, but usually stops at the eleventh. Anteriorly it is behind the fifth, sixth, seventh, eighth, and ninth costal cartilages and the ensiform cartilage. A part of the liver surface comes into direct contact with the anterior abdominal wall. From between the ninth and tenth rib cartilages the liver passes under the right costal arch into the epigastrium. Close under the ensiform process, at a spot usually called gastric fossa, lies a part of the liver which is turned forward and touches the abdominal wall more closely. In women with a "corset liver" the part in direct contact with the wall is much greater. Here some loops of intestine or transverse colon may intervene and a dulness will be found in percussing the mesogastrium, modified by a tympanic sound.

The under surface of the liver is in contact by its right lobe directly with the upper two-thirds of the right kidney, and internal to that, with the descending duodenum, and above both, near the vena cava, with the suprarenal capsule which also touches the posterior surface (His). Lateral to the gall-bladder is the colon, internal to it the quadrate lobe with the portio pylorica of the stomach in relation. Going to the left and above, we find the tuber omentale, and still more laterally the whole concavity of the left lobe covering the lesser curvature, the cardia, and adjacent part of the anterior surface of the stomach. In an empty contracted stomach it may cover the fundus.

The posterior edge and surface rest against the tenth and eleventh dorsal vertebrae and the posterior ends of those ribs. This part also rests on the crura of the diaphragm, covers the oesophagus, and embraces the vena cava. Against it are the aorta, thoracic duct, nerves, and small vessels which rise from the vertebral column, but are separated from the liver by the diaphragm.

The anterior edge of the liver follows, in the right hypochondrium, the tenth and eleventh ribs, but normally does not extend over the anterior end of the last. Should one in quiet respiration feel the liver lower than this point, there is enlargement or displacement. Between the ninth and tenth ribs the anterior edge of the
liver leaves the costal arch and passes obliquely from right to left, ascending to the anterior end of the left eighth rib. In case of a thin abdominal wall this anterior edge of the liver can be felt as it passes through the epigastrium. This part can contract adhesions with the wall.

Relations in Detail.

Antero-superiory:
Diaphragm;
Right and left lungs;
Pericardium and heart;
Anterior abdominal wall;

On the right:
Six or seven lower ribs;
Fifth to ninth costal cartilage.

Inferiory:
Right kidney and capsule;
Hepatic flexure of colon;
Descending duodenum;
Gall-bladder and cystic duct;
Vessels at portal fissure;
Pyloric end of stomach;
Superior curve of duodenum;
Cardia;
Lesser curvature of stomach;
Anterior surface stomach, small part (sometimes fundus of stomach).

Posteriory:
Diaphragm;
Tenth and eleventh dorsal vertebrae;
End of tenth and eleventh ribs;
Crura of diaphragm;
Esophagus;
Aorta;
Vena cava inferior;
Thoracic duct;
Non-peritoneal impression for right suprarenal capsule.

The Fixation of the Liver.—The liver, compared with other intraperitoneal organs, has a firm position, due to its fusion with the diaphragm. The peritoneal folds aid this fixation by connecting the liver to the concavity of the diaphragm. They are the falciform, or suspensory, coronary, and right and left lateral ligaments. In spite of this fixation, the liver experiences certain physiological changes and variations of position. It passes downward and forward in inspiration, and in expiration is pushed upward and backward. It moves up and down 1 to 1.5 cm. In inspiration Hasse finds a stretching of the liver; in expiration, a compression. These changes exert an influence over the circulation of the liver. The dilatation of the vessels accompanying the expansion of the liver during inspiration favors the influx of portal blood; during expiration and the accompanying compression the blood in the open hepatic veins is pressed into the vena cava.

Also the liver suffers small displacements occasioned by changes in the position of the body. In the horizontal supine position it falls back upon the diaphragm, and its anterior margin is more concealed behind the ribs. In the erect position the liver descends a little below the costal arch. The horizontal lateral position of body also has influence, displacing it a little toward the left or the right, as the case may be. Furthermore, by relaxation of ligaments, sometimes in women after childbirth, a "dislocation" of the liver results, or "wandering liver." Any pathological displacements of the diaphragm also affect the liver, as effusions into the thoracic cavity; also ascites, tympanites, or tumors in the abdominal cavity.
Vessels.—The blood-supply of the liver follows a double course through the portal vein and hepatic artery. The greatest amount of blood flowing through the liver, thus differing from other organs, comes from the veins of the digestive tract and of the spleen, which unite into a great vessel, the vena portarum or porta.

The hepatic artery and portal vein, accompanied by numerous lymphatics and nerves, ascend to the transverse fissure between the layers of the gastro-hepatic omentum. The hepatic duct, lying in company with them, descends from the transverse fissure between the layers of the same omentum. The relative position of the three structures is as follows: the hepatic duct lies to the right, the hepatic artery to the left, and the portal vein behind and between the other two. They are enveloped in a loose areolar tissue, the capsule of Glisson, which accompanies the vessels in their course through the portal canals in the interior of the organ.

In the transverse fissure this portal vein splits into two trunks, the right and left, for lobes of the same name. At the point of division is an enlargement, the sinus venarum porta. They enter the liver substance and subdivide dichotomously into smaller branches, which do not anastomose. They end in the interlobular connective tissue in three to five twigs, and form a rich plexus around each lobe, interlobular veins. These lose themselves in a capillary network, which penetrates the lobe in a ray-shaped manner, and are collected at its centre into a little vein, the vena centralis or intralobular vein. These are the roots of the hepatic veins.

The characteristic point of the blood-current of the portal system consists in this: it must first pass through a capillary circulation before it enters the inferior vena cava.

Accompanying the portal vein is the hepatic artery, a branch of the cælicic axis, which divides at the transverse fissure into a right and left branch. The twigs of the chief branches follow those of the portal vein, which accompany them singly or doubly. The hepatic artery supplies chiefly the connective tissue and the capsule of the liver. In the serous covering it anastomoses with the phrenic and internal mammary arteries.

The intralobular veins form, so to speak, the pedicles of the lobules, and, after their exit from each empty at an acute angle into bigger veins, the sublobular. These larger veins unite with each other and form numerous valveless hepatic veins, which, draining the blood from the circulation of the portal vein and hepatic artery, make their way to the posterior surface of the liver and empty, as three large trunks and a number of small ones, into the vena cava. These hepatic veins have no cellular investment, and their walls are directly adherent to the surrounding liver substance, while the branches of the portal vein, hepatic artery, and hepatic duct are enclosed by loose connective tissue, and the three go together in a portal canal.

When the arterial, portal, and biliary twigs are seen in the same connective tissue sheath, the portal twigs are the strongest, and the arteries have the smallest lumen.

On section of a piece of liver the open solitary holes are the cut hepatic veins, unable to collapse on account of their close relation to the liver-tissue. For this reason hemorrhage is so dangerous in wounds of the liver. The branches of the portal vein collapse on cross-section.

According to Sappey, there are five sets of accessory portal veins. The liver does not receive all its blood from the hepatic artery and vena portae.

The first group occupies the lesser omentum, and consists of venules from the lesser curvature of the stomach. When the pyloric vein rises high it joins this group, which is distributed to the lobes just in front of and just behind the transverse fissure.

The second group is more important, and consists of twelve to fifteen little veins rising from the fundus of the gall-bladder and distributed to the fossa vesicalis. Two cystic veins here usually open into the right branch of the portal vein.

The third group includes all the venules rising in the walls of the portal vein, hepatic artery, and hepatic duct. They lose themselves in the subjacent lobules.

The fourth group consists of veins descending from the middle portion of the
The falciform ligament. They ramify in the lobes adjoining the ligament. They are almost capillary and anastomose with each other.

The fifth group is formed of veins passing from the subumbilical part of the abdominal wall to the left longitudinal fissure of the liver. They are situated in the inferior part of the falciform ligament. The most important end at the umbilical incisure of the liver; others end in the umbilical fissure; and others, very delicate, surround the round ligament: one or two constantly empty into the left portal branch. At their origin these veins communicate with the epigastric veins, internal mammary, and the tegumentary veins of the abdomen.

The fourth and fifth groups do not come from the alimentary tract, and hence establish an anastomosis between the portal and general venous systems. These branches would dilate in some chronic diseases of the liver and aid the obstructed portal system.

The hepatic duct is formed at the transverse fissure by two tributaries, one from the right and one from the left lobe. The calibre of each nearly equals that of the trunk formed. The tributaries to these two branches start from the interlobular spaces in company with the portal and arterial twigs.

The lymph-vessels form a superficial and deep set.

The superficial lymph-vessels of the convex surface belong either to the posterior half or to the anterior half of the liver. Those of the posterior half form several groups, and from right to left are found first on the right edge, a larger lymph-vessel which runs around to the right lateral ligament, and from there to the inferior surface, and empties into a gland on the head of the pancreas.

Then comes a series of lymph-vessels which go over to the coronary ligament, and from there to the posterior surface of the liver, and empty into the lymphatic glands which lie on the inferior vena cava just above the Diaphragm. Along the falciform ligament from the right as well as from the left lobe is developed a rich network of vessels which unite into several larger trunks. These run between both layers of the falciform ligament, and join finally to form a big trunk which pierces the Diaphragm and empties into glands situated above this at its point of fusion with the pericardium.

Those vessels springing more laterally from the left lobe of the liver empty into glands situated more to the right, lying on the vena cava; the vessels rising to the left of the left lateral ligament, and from it, empty into glands situated on the lower part of the oesophagus.

Those vessels springing from the anterior half of the convex surface arch around the anterior margin of the liver and run into the glands situated in the transverse fissure. The vessels of the under surface also pass to those same glands. Only a few twigs arising on the posterior surface of the liver end in the glands lying on the vena cava.

Of the deeper lymph-vessels, some accompany the portal veins, and others the hepatic veins. The first, fifteen or eighteen in number, empty into the glands surrounding the neck of the gall-bladder. The last accompany the hepatic veins to the vena cava, five or six in number, and pass through the foramen venæ cave of the Diaphragm, and empty into glands situated just above it.

Microscopically the lymphatics are seen in Glisson’s capsule in the interlobular spaces, where they accompany the blood-vessels. They rise from lymph-spaces in the intralobular plexus.

The nerves come from two sources, left vagus and coeliac plexus. The left vagus after its passage through the oesophageal opening gives off twigs which turn from left to right along the lesser curvature of the stomach, between the two layers of the lesser omentum, to accompany the branches of the portal veins. Those twigs from the coeliac plexus are much more numerous, and come from three sources, right vagus, phrenic, and great sympathetic. They meet the hepatic artery and follow this to the transverse fissure. The nerves all divide into right and left sets, which accompany the branches of the artery, of the portal vein, and the tributaries of the hepatic duct. They terminate in fine tree-like endings, show-
ing varicosities, and are distributed to the blood-vessels and ducts, and to spaces between the liver-cells, and follow the biliary canaliculi (Berkeley). The phrenic nerves supply part of the external surface of the liver.

Structure.—The substance of the liver is composed of lobules held together by an extremely fine areolar tissue, and of the ramifications of the portal vein, hepatic duct, hepatic artery, hepatic veins, lymphatics, and nerves, the whole being invested by a serous and a fibrous coat.

The serous coat is derived from the peritoneum, and invests the greater part of the surface of the organ. It is intimately adherent to the fibrous coat.

The fibrous coat lies beneath the serous investment and covers the entire surface of the organ. It is difficult of demonstration, excepting where the serous coat is deficient. At the transverse fissure it is continuous with the capsule of Glisson, and on the surface of the organ with the areolar tissue separating the lobules.

The lobules form the chief mass of the hepatic substance; they may be seen either on the surface of the organ or by making a section through the gland.

They are small granular bodies about the size of a millet-seed, measuring from one-twentieth to one-tenth of an inch in diameter. In the human subject their outline is very irregular, but in some of the lower animals (for example, the pig) they are well-defined, and when divided transversely have a polygonal outline. If divided longitudinally they are more or less foliated or oblong. The bases of the lobules are clustered round the smallest radicles (sublobular) of the hepatic veins, to which each is connected by means of a small branch which issues from the centre of the lobule (intralobular). The remaining part of the surface of each lobule is imperfectly isolated from the surrounding lobules by a thin stratum of areolar tissue in which is contained a plexus of vessels (the interlobular plexus) and ducts. In some animals, as the pig, the lobules are completely isolated one from another by this interlobular areolar tissue.

If one of the sublobular veins be laid open, the bases of the lobules may be seen through the thin wall of the vein on which they rest, arranged in the form of a tesselated pavement, the centre of each polygonal space presenting a minute aperture, the mouth of an intralobular vein (Figs. 669 and 671).

Microscopic Appearance.—Each lobule is composed of a mass of cells (hepatic cells) surrounded by a dense capillary plexus, composed of vessels which penetrate from the circumference to the centre of the lobule, and terminate in a single
straight vein, which runs through its centre, to open at its base into one of the radicles of the hepatic vein. Between the cells are also the minute commencements of the bile-ducts. Therefore in the lobule we have all the essentials of a secreting gland; that is to say: (1) cells, by which the secretion is formed; (2) blood-vessels, in close relation with the cells, containing the blood from which the secretion is derived; and (3) ducts, by which the secretion, when formed, is carried away. Each of these structures will have to be further considered.

(1) The hepatic cells are of more or less spheroidal form, but may be rounded, flattened, or many-sided from mutual compression. They vary in size from the $\frac{1}{100}$ to the $\frac{1}{400}$ of an inch in diameter. They consist of a honeycomb network (Klein) without any cell-wall, and contain one or sometimes two distinct nuclei. In the nucleus is a highly refracting nucleolus with granules. Embedded in the honeycomb network are numerous yellow particles, the coloring matter of the bile, and oil-globules. The cells adhere together by their surfaces so as to form rows, which radiate from the centre to the circumference of the lobules. As stated above, they are the chief agents in the secretion of the bile.

(2) The Blood-vessels.—The blood in the capillary plexus around the liver-cells is brought to the liver principally by the portal vein, but also to a certain extent by the hepatic artery. For the sake of clearness the distribution of the blood derived from the hepatic artery may be considered first.

The hepatic artery, entering the liver at the transverse fissure with the portal vein and hepatic duct, ramifies with these vessels through the portal canals. It gives off vaginal branches which ramify in the capsule of Glisson, and appear to be destined chiefly for the nutrition of the coats of the large vessels, the ducts, and the investing membranes of the liver. It also gives off capsular branches which reach the surface of the organ, terminating in its fibrous coat in stellate plexuses. Finally it gives off interlobular branches which form a plexus on the outer side of each lobule, to supply its wall and the accompanying bile-ducts. From this, lobular branches enter the lobule and end in the capillary network between the cells. Some anatomists, however, doubt whether it transmits any blood directly to the capillary network.

The portal vein (Fig. 670) also enters at the transverse fissure and runs through the portal canals, enclosed in Glisson's capsule, dividing into branches in its course, which finally break up into a plexus (the interlobular plexus) in the interlobular spaces between the lobules. In their course these branches receive the vaginal and capsular veins, corresponding to the vaginal and capsular
branches of the hepatic artery (Fig. 670). Thus it will be seen that all the blood carried to the liver by the portal vein and hepatic artery, except perhaps that derived from the interlobular branches of the hepatic artery, directly or indirectly finds its way into the interlobular plexus. From this plexus the blood is carried into the lobule by fine branches which pierce its wall and then converge from the circumference to the centre of the lobule, forming a number of longitudinal vessels which are connected by transverse or horizontal branches (Fig. 671). In the interstices of the network of vessels thus formed are situated, as before said, the liver-cells: and here it is that, the blood being brought into intimate connection with the liver-cells, the bile is secreted. Arrived at the centre of the lobule, all these minute vessels empty themselves into one vein, of considerable size, which runs down the centre of the lobules from apex to base and is called the **intralobular vein**. At the base of the lobule this vein opens directly into the **sublobular vein**, with which the lobule is connected, and which, as before men-

![Figure 672](image)

**Fig. 672.**—Origin of the hepatic veins. (Sappey.) 1. Sublobular vein. 2, 2. Intralobular veins. 3, 3. Tributaries to 2. 4, 4. Capillary network between portal and hepatic systems.

 tioned, is a radicle of the hepatic vein (Fig. 672). The sublobular veins, uniting into larger and larger trunks, end at last in the hepatic veins, which do not receive any intralobular veins. Finally, the hepatic veins, as mentioned at page 1057,

![Figure 673](image)

**Fig. 673.**—Section of liver.

![Figure 674](image)

**Fig. 674.**—A transverse section of a small portal canal and its vessels. (After Kiernan.) 1. Portal vein. 2. Interlobular branches. 3. Vagal branches. 4. Hepatic duct. 5. Hepatic artery.

converge to form three large trunks which open into the inferior vena cava, while that vessel is situated in the fissure appropriated to it at the back of the liver.
(3) The Duets.—Having shown how the blood is brought into intimate relation with the hepatic cells in order that the bile may be secreted, it remains now only to consider the way in which the secretion, having been formed, is carried away. Several views have prevailed as to the mode of origin of the hepatic ducts; it seems, however, to be clear that they commence by little passages which are formed between the cells, and which have been termed intercellular biliary passages or bile-canaliculi (Fig. 673). These passages are merely little channels or interspaces left between the contiguous surfaces of two cells or in the angle where three or more liver-cells meet, and it seems doubtful whether there is any delicate membrane forming the wall of the space. The channels thus formed radiate to the circumference of the lobule, and, piercing its wall, form a plexus (interlobular) between the lobules. From this plexus ducts are derived which pass into the portal canals, become enclosed in Glisson’s capsule, and, accompanying the portal vein and hepatic artery (Fig. 674), join with other ducts to form two main trunks, which leave the liver at the transverse fissure, and by their union form the hepatic duct.

Structure of the Duets.—Those in the interlobular spaces have walls of connective tissue lined by columnar epithelium. They probably contain muscle-cells arranged longitudinally and circularly. As they lie in the lobule the columnar epithelium is very short and flat and the lumen very small. The bile-canaliculi open directly into them, liver-cells abutting against the epithelium. The ducts in the portal canals are larger, and present numerous openings on the inner surface, sometimes arranged in two rows. Sappey considers them the orifices of mucous glands (Fig. 675), and compares their appearance to that of the vegetable parasites. Their function is much discussed, and at present they are regarded only as tubular recesses. They occasionally anastomose, and from their sides sacular dilatations are given off.

Sometimes certain parts of the liver gradually atrophy or completely disappear, while the corresponding biliary ducts remain and, on the contrary, become hypertrophied. They are called vasa aberrantia. They are not found in the fetus or child, are not rare in the adult, and are most frequent in old age. Accompanying them are all the other vessels which supplied the part, branches of the portal vein, hepatic vein, and artery. They are situated at either extremity of the liver, most often in the left lateral ligament, at the attachment of the falciform, or in the positions of atrophied “bridges,” as over the left longitudinal fissure or vena cava (Fig. 676). They present certain common characteristics. All communicate with
the biliary ducts; they have a yellowish color, have epithelial lining, and fibrous coat, and in proportion as the lobe has atrophied, they have hypertrophied. They present the tubular recesses, and anastomose with each other. These vessels are found in certain mammals.

The Excretory Apparatus of the Liver.—This apparatus consists of the bile-canaliculi and ducts, which we have seen in and between the lobules; of the hepatic duct formed by the union of these; of a diverticulum or reservoir the gall-bladder; of the communicating tube, cystic duct, and of the united cystic and hepatic ducts, the common bile-duct or ductus choledochus (Fig. 677).

![Fig. 677.—Biliary vessels and gall-bladder, dried and insufflated. (Tillaux.)](image-url)

The hepatic duct is formed by the union of the right and left bile-ducts descending from the liver. They unite at an obtuse angle at the right end of the transverse fissure. Their point of union is usually near the spot where they emerge from the liver. Often this happens lower down and the hepatic duct is shortened. Its usual length is 3–5 cm. (one to two inches) and diameter 4 mm. It joins with the cystic duct at an acute angle to form the common bile-duct. It descends in the right margin of the gastro-hepatic omentum with the vena cava behind and the hepatic artery to the left. The passage of bile into the gall-bladder only occurs when its exit to the duodenum is closed. The bile then from the beginning of the common duct has a passage provided upward and backward to a reservoir which is the gall-bladder.
The gall-bladder is pear-shaped. It is directed, with its broader rounded end downward and forward, and to the right to the anterior margin of the liver, and with its sharper end backward and upward toward the transverse fissure. It is 7 to 8 cm. long (three or four inches) and near the fundus 2.5–3 cm. broad (over an inch), and will contain 30–50 cc. of bile (1-1½ ounces). There are to be distinguished a fundus, a body, and a neck. It is fastened to the liver by connective tissue and vessels, and lies in the fossa vesicalis. The fundus extends beyond the anterior margin of the liver in the region of the incisura vesicalis. But in a normal position of the liver, the gall-bladder may be placed more or less behind this edge. The position of the fundus is usually at the lower edge of the ninth costal cartilage on the outer edge of the right Rectus muscle. Here it rests directly on the abdominal wall. When it extends beyond the liver it can be percussed. Its function is more than a storehouse. It forms some of the constituents of the bile. Exceptionally it lies more to the right or more to the left.

The fundus rests usually on the transverse colon and farther back on the upper end of the descending duodenum, or on the pylorus. This part is usually stained by biliary coloring matter after death. The neck of the bladder usually extends in the posterior and upper part of the vesical fossa close to the transverse fissure. It is continued in a spiral curve into the cystic duct. This curving corresponds on the inner surface to a constant more or less well developed screw-like valve which runs through the whole cystic duct, Valeula Heisteri.

The upper surface is attached to the liver by areolar tissue and vessels. Its under surface and fundus are covered by peritoneum reflected from the liver surface. Sometimes the peritoneum completely surrounds the bladder, suspending it by a mesentery from the under surface of the liver. The gall-bladder is not present in all vertebrates. It is lacking in some mammals and birds, but is present in all reptiles, and nearly all fishes. The ass, horse, elephant, and rhinoceros do not have it.

Relations of the Gall-bladder.

Superiorly:
Liver (Fossa vesicalis).

Anteriorly:
Abdominal wall; and ninth costal cartilage.

Inferiorly:
Heptatic flexure of colon;
Beginning of transverse colon;
Duodenum, first and second parts;
Pyloric end of stomach.

Vessels and Nerves.—It is supplied by the cystic artery from the right branch of the hepatic. Two cystic veins usually empty into right branch of the vena portae. Twelve or fifteen from the fundus go directly into liver.

The nerves are from the coeliac plexus.

The lymphatics are numerous and empty into a gland on the neck of the bladder.

The cystic duct, the smallest of the three, running from the neck of the gall-bladder is 3–7 cm. long (one to three inches) and 2.3 mm. wide. Its course is toward the left, at first a little curved and then straight. It joins the hepatic duct at an acute angle to form the common duct. This is contained in the edge of the lesser omentum.

The ductus choledochus (κοληδός, bile, δωξός, which receives) is the largest of the three, and is the common excretory duct of both liver and gall-bladder and conveys the bile to the duodenum. The length is various depending upon the point of meeting of its two tributaries: 7–8 cm. (Sappey); 2–4.5 (Luschka); 6–7 cm., or about three inches (Joessel), and 5.6 mm. to 7.5 mm. wide (one-fourth inch). It
continues the course of the hepatic duct, running downward and backward in the hepato-duodenal ligament in front of the portal vein and to the right of the hepatic artery. It passes behind the first portion of the duodenum and then behind and to the inner side of the second portion, lying here in a furrow between duodenum and head of pancreas; or it may be enclosed by the pancreas till it meets the pancreatic duct. For a short space it is in contact with the right side of this duct. The two perforate the duodenal wall and run obliquely for three-fourths of an inch between the coats. They finally open into a little pouch and that upon a papilla of the mucous membrane by a common orifice, situated near the junction of middle and lower third of the duodenum on its posterior internal wall. This is three or four inches beyond the pylors. (See Pancreas.)

When the gall-bladder is distended with bile or calculi, the fundus may be felt through the abdominal parietes, especially in an emaciated subject: the relations of this sac will also serve to explain the occasional occurrence of abdominal biliary fistule, through which biliary calculi may pass out, and of the passage of calculi from the gall-bladder into the stomach, duodenum, or colon, which occasionally happens.

Structure.—The gall-bladder consists of three coats—serous, fibrous and muscular, and mucous.

The external or serous coat is derived from the peritoneum; it completely invests the fundus, but covers the body and neck only on their under surface.

The fibro-muscular coat is a thin but strong layer which forms the framework of the sac, consisting of dense fibrous tissue which interlaces in all directions and is mixed with plain muscular fibres which are disposed chiefly in a longitudinal direction, a few running transversely.

The internal or mucous coat is loosely connected with the fibrous layer. It is generally tinged with a yellowish-brown color, and is everywhere elevated into minute rugae, by the union of which numerous meshes are formed, the depressed intervening spaces having a polygonal outline. The meshes are smaller at the fundus and neck, being most developed about the centre of the sac.

The mucous membrane is covered with columnar epithelium and secretes an abundance of thick viscid mucus; it is continuous through the hepatic duct with the mucous membrane lining the ducts of the liver, and through the ductus communis choledochus with the mucous membrane of the alimentary canal.

In the cystic duct the mucous membrane is raised into oblique crescentic folds much as in the neck of the bladder. It presents the appearance of a continuous spiral valve of which we have seen indications in the small intestine and rectum (Fig. 678). This is the valve of Heister (1758). The outer surface of the duct presents indentations at the attachment of these folds, giving it a sacculated or twisted appearance (Fig. 677).

The coats of the larger ducts are an external or fibrous and an internal or mucous. The fibrous coat is composed of strong fibro-areolar tissue, with a certain amount of muscular tissue arranged for the most part in a circular manner around the duct. The mucous coat is continuous with the lining membrane of the hepatic duct and gall-bladder, and also with that of the duodenum, and, like the mucous membrane of these structures, its epithelium is of the columnar variety. It is provided with numerous tubules, which are lobulated and open by minute orifices scattered irregularly (Fig. 675).

Surface Form.—The liver is situated in the right hypochondriac and the epigastric regions, and is moulded to the arch of the Diaphragm. In the greater part of its extent it lies under cover of the lower ribs and their cartilages, but in the epigastric region it comes in contact with the abdominal wall in the subcostal angle. The upper limit of the right lobe of the liver may be defined by a line drawn from the articulation of the fifth right costal cartilage to the sternum horizontally outward to a little below the nipple, and then inclined downward to reach the seventh rib at the side of the chest. The upper limit of the left lobe may be defined by continuing this line to the left, with an inclination downward as it crosses the gladiolus, to a point about
two inches to the left of the sternum on a level with the sixth left costal cartilage. The lower limit of the liver may be indicated by a line drawn half an inch below the lower border of the thorax on the right side as far as the ninth right costal cartilage, and thence obliquely upward along the subcostal angle to the eighth left costal cartilage. A slight curved line with its convexity to the left from this point—i.e. the eighth left costal cartilage—to the termination of the line indicating the upper limit will denote the left margin of the liver. The fundus of the gall-bladder approaches the surface behind the anterior extremity of the ninth costal cartilage, close to the outer margin of the Right rectus muscle.

It must be remembered that the liver is subject to considerable alterations in position, and the student should make himself acquainted with the different circumstances under which this occurs, as they are of importance in determining the existence of enlargement or other diseases of the organ.

Its position varies according to the posture of the body. In the erect position in the adult male the edge of the liver projects about half an inch below the lower edge of the right costal cartilages, and its anterior border is felt by the point of the left index finger. In this situation if the abdominal wall is thin. In the supine position the liver gravitates backward and recedes above the lower margin of the ribs, and cannot then be detected by the finger. In the prone position it falls forward, and can then generally be felt in a patient with loose and lax abdominal walls. Its position varies also with the ascent or descent of the Diaphragm. In a deep inspiration the liver descends below the ribs; in expiration it is raised behind them. Again, in emphysema, where the lungs are distended and the Diaphragm descends very low, the liver is pushed down. In some other diseases, as phthisis, where the Diaphragm is much arched, the liver rises very high up. Pressure from without, as in tight-lacing, by compressing the lower part of the chest, displaces the liver considerably, its anterior edge often extending as low as the crest of the ileum; and its convex surface is often at the same time deeply indented from the pressure of the ribs. Again, its position varies greatly according to the greater or less distension of the stomach and intestines. When the intestines are empty the liver descends in the abdomen, but when they are distended it is pushed upward. Its relations to surrounding organs may also be changed by the growth of tumors or by collections of fluid in the thoracic or abdominal cavities.

Surgical Anatomy.—On account of its large size, its fixed position, and its friability, the liver is more frequently ruptured than any of the abdominal visera. The rupture may vary considerably in extent, from a slight scratch to an extensive laceration completely through its substance, dividing it into two parts. Sometimes an internal rupture without laceration of the peritoneal covering takes place, and such injuries are most susceptible of repair; but small tears of the surface may also heal; when, however, the laceration is extensive, death usually takes place from hemorrhage, on account of the fact that the hepatic veins are contained in rigid canals in the liver-substance and are unable to contract, and are moreover unprovided with valves. The liver may also be torn by the end of a broken rib perforating the Diaphragm. The liver may be injured by stabs or other punctured wounds, and when these are inflicted through the chest-wall both pleural and peritoneal cavities may be opened up and both lung and liver be wounded. In cases of wound of the liver from the front, hernia of a part of this viscus may take place, but can generally easily be replaced. Abscess of the liver is of not unfrequent occurrence, and may open in many different ways on account of the relations of this viscus to other organs. Thus, it has been known to burst into the lungs, and the pus been coughed up, or into the stomach and the pus vomited; it may burst into the colon or into the duodenum; or, by perforating the Diaphragm, it may empty itself into the pleural cavity. Frequently it makes its way forward and points on the anterior abdominal wall, and finally it may burst into the peritoneal or parahyoid cavities. Abscesses of the liver frequently require opening, and this should be done preferably by an incision in the right subcostal line, in two stages: the peritoneal cavity being opened and the liver over the summit of the abscess being stitched to the parietal peritoneum on the first occasion, and three or four days subsequently the abscess being evacuated. Hydatid cysts are more often found in the liver than in any other of the visera. The reason of this is not far to seek. The embryo of the egg of the canine echinococci, being liberated in the stomach by the disintegration of its shell, bores its way through the gastric wall, and usually enters a blood-vessel and is carried by the blood-stream to the hepatic capillaries, where its onward course is arrested, and where it undergoes development into the fully-formed hydatid. When the gall-bladder is ruptured, or one of its main ducts, which may occur independently of laceration of the liver, the injury is necessarily fatal from peritonitis caused by the extravasation of bile into the peritoneal cavity. The gall-bladder may become distended with bile in cases of obstruction of its duct or the common bile-duct, or from a collection of gall-stones within its interior, thus forming a large tumor. The swelling is pear-shaped, and projects downward and forward to the umbilicus. It moves with respiration, since it is attached to the liver. To relieve this condition the gall-bladder must be opened and the gall-stones removed. The operation is performed by an incision two or three inches long in the right subcostal line, commencing an inch below the costal margin. The peritoneal cavity is opened, and, the tumor having been found, sponges are packed round it to protect the peritoneal cavity, and it is aspirated. When the contained fluid has been evacuated the gall-bladder is drawn out of the abdominal wound and its wall incised to the extent of an inch; any gall-stones in the bladder are now removed and the interior of the sac sponged dry. If the case is one of obstruction of the duct, an attempt must be made to dislodge
the stone by manipulation through the wall of the duct, or it must be crushed from without by carefully padded forceps. After all obstruction has been removed a drainage-tube is to be inserted and the external wound closed around it, the stitches being passed through the parietal peritoneum and also through the peritoneum covering the gall-bladder around the incision, so as to bring these two surfaces into apposition. The fistulous opening generally closes in the course of a few weeks.

THE PANCREAS.

Dissection.—The pancreas may be exposed for dissection in three different ways: 1. By raising the liver, drawing down the stomach, and tearing through the gastro-hepatic omentum and the ascending layer of the transverse meso-colon. 2. By raising the stomach, the arch of the colon, and great omentum, and then dividing the inferior layer of the transverse meso-colon and raising the ascending layer of the transverse meso-colon. 3. By dividing the two layers of peritoneum which descend from the great curvature of the stomach to form the great omentum, turning the stomach upward, and then cutting through the ascending layer of the transverse meso-colon (see Figs. 606 and 616).

The pancreas (πάν-χρέας, all flesh) or the abdominal salivary gland, is a compound racemose gland, similar in structure to the salivary glands, though softer and less compact. It is long and lies transversely across the posterior wall of the abdomen and when hardened in situ is prismatic, with three surfaces. But usually, when removed from the body, it appears flattened, with only two surfaces and two borders. It lies deep in the epigastrium at the level of the second lumbar vertebra; behind the stomach; between the duodenum on the right and the spleen on the left, so that for clinical and surgical purposes it is scarcely approachable. In shape, Meckel compared it to a sort of hammer; Verneuil, to a cross placed on its side, the short vertical arm representing the head. Winslow compared it to a dog’s tongue. Its right extremity being broad is termed the head; then follows a constriction made by the two terminal parts of the duodenal loop called the neck, which connects head and body. The body is the free portion passing to the left, and finally it abuts against the spleen as the tail (Figs. 634 and 679).

![Fig. 679.—Pancreas and adjoining viscera from before. His' model. (F. E.)](image)

In color the pancreas is grayish-white in the intervals of digestion, turning to a rosy hue during secretion.

Its volume presents many variations. In general it is bigger in man than in woman. It is usually 15-16 cm. long (six inches); its width is not one-fourth or one-fifth of its length; its thickness is 15-18 mm. (one-half to one inch). Length, 23 cm.; width, 4.5 cm.; thickness, 2.8 cm. (Luschka). Its volume is 54-90 c.c. Its weight is about 70 gm. in the male and 60 in the female, two and one-fourth to three and a half ounces. A maximum weight is 105 gm.

The head of the pancreas is called disc-shaped, or, since it is elongated both above and below, hammer-shaped. It is flattened from before backward, and conforms to the whole concavity of the duodenum made up of its four parts, and not vice
versa. Its edges overlap the surface of the duodenum and may be connected by muscular tissue. There is an interruption at one place, below and to the left in front of the preaortic portion of the duodenum, where the root of the mesentery passes, in which are contained the superior mesenteric vessels, the vein to the right and the artery to the left (Figs. 634 and 679). Both vessels run in a groove on the posterior surface of the head, and near the descending duodenum in a groove or canal is the common bile-duct. A part of the pancreatic tissue is bent around behind the vessels, which is called the lesser head. The posterior
surface of the head is bound by loose tissue to and rests upon the inferior vena cava and right crus of diaphragm, coeliac plexus, left renal vein, and right renal vessels; the descending duodenum intervenes between it and the right kidney. Near its lower end it is crossed in front by the transverse colon and transverse mesocolon. The superior and inferior pancreatico-duodenal vessels are in front of the head.

The neck is about one inch long, passing upward and forward to the left; it is bounded above by the first part of the duodenum and below by the end of the ascending portion. The stomach, if distended, touches this portion by the posterior surface of the pylorus. Behind it is the junction of the superior mesenteric vein with the vena portae (Fig. 681). To the right it is grooved by the gastro-duodenal and superior pancreatico-duodenal arteries.

The body and tail constitute the prismatic portion presenting three surfaces and three borders: anterior, posterior, and inferior surfaces; superior and two inferior borders. Some regard the surfaces as posterior, antero-superior, and antero-inferior, making an anterior border more distinct. This part of the pancreas passes from the right to the left and is moulded to different structures, following the example of the liver. Its anterior surface is fitted to the convexity of the filled stomach; its posterior surface is more flat except where it covers the left kidney; the tail passes upward and backward to the spleen. The anterior surface is concave, looks upward and forward; the posterior surface of the stomach lies upon it, separated by the bursa omentalis, or two layers of the lesser sac. Perforating ulcers of the stomach can reach the pancreas and result in fusion of these two organs, or in hemorrhage from the splenic vessels.

The posterior surface (Figs. 680 and 681) corresponds internally to the aorta and left crus of the diaphragm and the origin of the superior mesenteric artery. It crosses the second or third lumbar vertebra. Near the upper edge are two furrows—one for the somewhat tortuous splenic artery and a straight one for the splenic vein. The surface shows a shallow furrow for the splenic vein, which ascends from the middle of the lower edge toward the left to the upper edge. This edge carries a furrow from the middle along the left half, in which the splenic artery takes part of its course. The splenic vein in its outer half runs above the edge to reach the hilus of the spleen. To the left is the left kidney and its vessels, and sometimes the left suprarenal capsule. The relations to the left kidney show two types: one is seen in the His models and Fig. 636, where the pancreas runs directly over the hilus and centre of the kidney, exposing the suprarenal capsule, and a considerable part of the anterior kidney surface above, the tail touching the lower part of the spleen.

The other type is seen in Fig. 634. Here the pancreas is higher, and crosses the upper part of the kidney, leaving exposed above its edge the whole or only a part of the left suprarenal capsule. The tail touches the same part of the spleen in each case, showing it is also elevated with the pancreas. (Compare Figs. 634 and 679.)

The inferior surface is narrow, only 1 to 2 cm. broad, and shows, in the organ hardened in situ, internally a cavity and laterally a convexity, each directed downward. It rests by the concavity on the duodeno-jejunal flexure, and often on some coils of the jejunum, and to the left on the transverse colon.

The superior border of the body of the right is prominent, blunt, and flat; laterally, near the tail, it is narrower and sharper. The inner blunt elevation is covered by the lesser omentum, and fits into and behind the lesser curvature of the stomach; it is the tuber omentale of the pancreas. Between it and the tuber omentale of the liver is the lesser sac. This border is related above to the celiac axis and solar plexus, and to two of the branches of the former, the hepatic artery passing to the right, the splenic to the left.

The inferior or anterior border is the dividing line for the two layers of the transverse mesocolon. The upper layer passes up over the anterior surface and here constitutes the posterior wall of the lesser sac. The lower layer passes down
over the narrow inferior surface (Fig. 679). Thus the posterior surface is devoid of peritoneum.

The tail of the pancreas rests upon the lower part of the inner surface of the spleen, or is bound to it by a fold of peritoneum, the lig. pancreatico-lienale. It crosses over the middle of the left kidney, or kidney and capsule, or capsule alone. In front of this portion is the left gastro-epiploic artery.

The excretory duct of the gland, ductus pancreaticus or canal of Wirsung runs (1643) from left to right in the long axis of the gland, sometimes approaching the anterior surface, but more often the posterior surface. It begins with a very small calibre, formed by union of small ducts from the lobules, in the tail part, and gradually increases in size on the receipt of tributaries from every side; so that near its mouth it attains the size of the classical quill, about one-ninth of an inch in diameter. It can be found by its white color and close relation to the large pancreatic artery. After reaching the neck it turns downward, backward, and to the right in the head, and reaches the left side of the common bile-duct, and both go to the descending duodenum.

It receives numerous branches in the head of the gland, a large one from below, and the ductus pancreaticus accessorius or ductus Santorini from above (1775) (Fig. 682). This latter duct opens into the duodenum independently on a papilla about one inch above the orifice of the others.\footnote{This is of interest, as the pancreas originally budded from the duodenum as two outgrowths. At about the sixth week the processes and their ducts join, as here seen.}

This course of its contents, however, is below into the pancreatic duct. Should this become occluded near its orifice then a reverse flow might occur in the duct of Santorini.

The bile and pancreatic ducts do not unite outside the duodenal wall. They enter it obliquely and run obliquely a short distance between its coats and then unite at an acute angle and empty into a common receptacle just under the mucous membrane (Fig. 683). This little bladder-like pouch is called the diverticulum Vateri (1720). It throws up a papilla of mucous membrane situated on the free edge of one of the valvular conniventes. This is the papilla of Vater. It has a single opening, which can be best found by the presence of a drop of fluid intruded by pressure on the gall-bladder or pancreas. The papilla is still farther concealed by a mucous fold, which covers it from above (Fig. 683).

Abnormal forms occur; the descending duodenum may be surrounded by a ring of pancreatic tissue; the tail may be bifid; a part of the head curving around behind the mesenteric vessels may form the lesser pancreas. Accessory glands (pancreas accessorium) are found most often in the walls of the jejunum and in those of the stomach.
Relations in Detail (Fig. 684).

**Superiorly:**
- First part of duodenum;
- Coeliac axis, solar plexus;
- Splenic and hepatic arteries;
- Tuber omentale of liver.

**Anteriorly:**
- Bursa omentalis (lesser sac);
- Posterior surface of stomach;
- Gastro-duodenal artery;
- Pancreatico-duodenal arteries;
- Upper layer of transverse mesocolon;
- Transverse colon.

**To right:**
- Concavity of duodenum.

**To left:**
- Lower part of inner surface of spleen.

**Posteriorly:**
- Second (third or first) lumbar vertebra;
- Pancreatic and common bile-ducts;
- Vena cava inferior;
- Origin of thoracic duct;
- Crura of diaphragm;
- Coeliac plexus;
- Aorta;
- Sup. mesenteric artery;
- Splenic, sup. and inf. mesenteric veins;
- Vena portæ;
- Right and left renal vessels;
- Left kidney (or kidney and capsule or capsule alone).
Inferiorly:
Duodeno-jejunal flexure;
Third and fourth parts of duodenum;
Jejunum;
Transverse colon;
Lower layer of transverse mesocolon;
Superior mesenteric vessels;
Inferior mesenteric vein;
Mesentery.

Vessels and Nerves.—The pancreas is the only abdominal organ which does not have a special artery from the aorta. Its supply comes from the celiac axis and superior mesenteric. The splenic artery gives the pancreaticæ parvae and pancreatica magna, which supply the tail and body. The pancreatico-duodenalis superior comes from the gastro-duodenalis of the hepatic. These all come from the celiac axis. The superior mesenteric gives off the pancreatico-duodenalis inferior, which, with the superior, supplies the head.

The veins are of the same names, and empty into the splenic and superior mesenteric veins, all belonging to the portal system.

The lymphatic vessels are numerous, divided, according to their course, in upper, lower, right, and left sets (Sappey).

The upper open into a row of lymph-glands along the splenic artery; the lower open into glands on the posterior surface around the superior mesenteric vessels; the right open into three or four glands found between the head of the pancreas and descending duodenum; the left, into a group of glands situated between the tail of the pancreas and spleen in the pancreatico-lencial ligament.

The nerves rise from the celiac plexus, and probably have some elements of the right vagus, and accompany the vessels which supply the pancreas; the most of them go with the splenic artery. They are non-medullated and gangliated. In the gland they run independently of the vessels.

In structure the pancreas closely resembles the parotid gland. It differs in certain particulars, and is looser and softer in its texture. It is not enclosed in a distinct capsule, but is surrounded by areolar tissue which dips down into its interstices and divides the gland tissue into lobes, and these are subdivided by septa into lobules which in turn are composed of groups of alveoli, connected

![Diagram of pancreas](image)
with one of the ramifications of the main duct (Fig. 685). This interalveolar connective tissue supports the blood-vessels, and in certain parts of it are seen collections of cells, interalveolar cell-islets. They are permeated by a network of capillaries, and are very characteristic of the pancreas. Their function is unknown. The minute ducts are lined by short columnar epithelium, shorter than that found in the salivary ducts, and with no striation. The alveoli are tubular, wavy, and convoluted, lined by columnar cells which presents two zones: an outer one presenting the nucleus, clear and faintly striated; and an inner granular one, next the lumen. These are the secreting cells; after their activity the granular zone occupies most of the cell, whereas, in the earliest stage of digestion, the clear zone did this. The lumen of the alveolus is hardly visible, being filled by spindle-shaped cells, the centro-acinar cells of Langerhaus. Piersol considers these as imperfectly developed acini, and calls them bodies of Langerhaus.

The pancreatic duct presents two coats, fibro-elastic and mucous. There is no sign of muscular tissue. Fine intercellular canaliculi have been seen, comparable to those of the liver, passing from between the cells to the lumen of an alveolus.

Surface Form.—The pancreas lies in front of the second lumbar vertebra, and can sometimes be felt, in emaciated subjects, when the stomach and colon are empty, by making deep pressure in the middle line about three inches above the umbilicus.

Surgical Anatomy.—The pancreas presents but little of surgical importance. It is occasionally the seat of cancer, which usually affects the head or duodenal end, and therefore often speedily involves the common bile-duct, leading to persistent jaundice. Cysts are also occasionally found in it, which may present in the epigastric region, above and to the right of the umbilicus, and may require opening and drainage. The fluid in them contains some of the elements of the pancreatic secretion and is very irritating, so that, if allowed to come in contact with the skin of the abdominal wall, it is likely to produce intractable eczema. It has been said that the pancreas is the only abdominal viscera which has never been found in a hernial protrusion; but even this organ has been found, in company with other visceræ, in rare cases of diaphragmatic hernia. The pancreas has been known to become invaginated into the intestine, and portions of the organ have sloughed off. In cases of excision of the pylorus great care must be exercised to avoid wounding the pancreas, as the escape of the pancreatic fluid may be attended with serious results. According to Billroth, it is likely, in consequence of its peptonizing qualities, to dissolve the cicatrix of the stomach.

THE SPLEEN.

The spleen is the largest and most important ductless gland. It is probably related to the vascular system, yet its anatomical relations to the stomach and physiological relation to the liver, may allow it to be described as an accessory to the digestive tract.

It is placed deep in the left hypochondrium, between the fundus of the stomach and diaphragm, above the descending colon.

In number there is but one, yet various observations show it may be congenitally lacking, or may be multiple; as many as twenty-three in one body. These are called accessory or supernumerary spleens (lienculi), probably occasioned by the deep notching of the anterior margin and separation of the included parts. They may be connected with the mother-organ by thin bridges of splenic tissue or only by a portion of capsule. They are generally wholly isolated, and situated in the gastro-splenic omentum, great omentum, transverse mesocolon, or in the pancreas on a branch of the splenic artery. Frequently, one or two are in the region of the hilus. They are of the size of a hazelnut, red to almost black in color and of a rounded form.

No organ varies more in volume than the spleen. In children it is relatively well developed. In old age it is usually atrophied. It varies with the same individual, with sex, degree of fulness of portal vein, state of health or of disease, and with the influence of certain drugs. It is hypertrophied in all infectious diseases and in all depending upon malarial poison or leukæmia. It may be so large as to reach the pelvis and weigh many pounds.

Its average length in ten adult men was found to be 12 cm. (five or six

68
inches; breadth, 8 cm.; thickness, 3 cm. (Sappey). In children its proportion to body-weight is 1 to 350; in adults 1 to 320; in old age 1 to 700.

Its average cadaveric weight in the above ten specimens was 195 gm. If filled with blood its physiological weight would be 225 gm. (or 7 ounces). Its specific gravity is 1.054, showing greater density than the liver. Its volume is 200 to 300 cc.

Its color in the living animal is dark red and probably the same in living man. After death it is dark purple to a grayish red, due to the presence of venous blood.

In consistence it is soft and distensible and liable to laceration.

Form and Relations.—The spleen may be ellipsoid, tongue-shaped in length, or it may be rectilinear with its four corners rounded off. An internal view of the model by His (Fig. 612), shows it to be somewhat broader above than below, while typical forms presented by Luschka show two types both larger below. One is rectangular which is most frequent, and one is oval (Fig. 686).

Three surfaces may be distinguished, phrenic or external, basal, and internal, which is subdivided by the intermediate ridge (margo intermedium) into an anterior gastric portion (superficies gastrica), and a posterior renal portion (superficies renalis).

There are two margins, anterior or crenated (margo crenatus, and posterior (margo obtusus).

The spleen lies obliquely with its long axis placed deep in the left hypochondrium and nearly parallel to the ribs. It lies between the concave surface of the diaphragm, placed to the left, behind and above, and the fundus of the stomach, placed to the right and in front. It is above the left kidney and splenic flexure of colon (Fig. 680). This figure will repay study as we do not always appreciate that the suprarenal capsule and kidney and spleen rise nearly to the cardia with the pancreas, transverse colon, and splenic flexure in immediate contact.

Its large convex phrenic surface lies against the costal part of the diaphragm and looks upward, backward, and to the left or even a little inward above. It is covered by the ninth, tenth, and eleventh ribs, but separated from them by the peritoneum, diaphragm, costo-phrenic sinus, and in part by the left pleura and lung. In some cases the left lobe of the liver extends between this surface of the spleen and diaphragm. This is normal at birth when the hepatic surface of the spleen is the biggest of all.

The internal surface directed toward the abdominal cavity is divided by a prominent ridge into two parts, of which the posterior is narrow and the anterior broad.

The hilus of the spleen may be on the ridge, but is usually anterior to it. It is represented by an irregular longitudinal row of depressions, in which the arteries and nerves enter and through which the lymphatics and veins emerge.

The surface posterior to the ridge is the renal surface, flat and not reaching as high as the gastric surface, it is turned inward and downward toward the left crus of the diaphragm, and is in contact with the upper and outer margin of the left kidney, and usually the suprarenal capsule.

The gastric surface, broad and concave, is directed inward and forward. When the stomach is distended in the greater part of its extent, this surface lies
against the posterior wall of the fundus and body of the stomach (Fig. 680). Lower down it touches the tail of the pancreas.

The basal surface forms the lower and outer end of the spleen, and is triangular in shape. This does not rest on the left kidney, but frequently is in contact with the tail of the pancreas and regularly with the splenic flexure of the colon and phreno-colic ligament.

The anterior or crenate margin is sharp and thin and usually marked by a few, two to four, notches more or less deeply cut. It separates the internal from the phrenic surface. Traced from the upper end of the spleen, this border passes outward, convex above. This lies between the diaphragm and stomach nearly as high as the cardia. The border then passes downward and forward, and is in close contact with the chest-wall at the mid-axillary line.

The inner or intermediate border lies on the interior surface posterior to the hilus, and separates the gastric and renal surfaces. The posterior or blunt border separates the internal and phrenic surfaces. It dips in between the diaphragm and left kidney, and runs downward and outward along the lower border of the
eleventh rib. A lower border may be described between the phrenic and basal surfaces.

The upper end of the spleen lies on the level of the tenth dorsal vertebra. It approaches the vertebral column to within 2 or 3 cm., and often touches it. It is covered behind by the ribs and the great Sacro-spinalis muscle.

The lower end of the spleen extends more or less forward, but normally, even in deep inspiration, does not extend beyond the costo-clavicular line, which connects the left sterno-clavicular articulation to the anterior end of the eleventh rib. Frequently it only reaches the axillary line. In regard to the relations of the spleen to the thoracic cavity and lung three zones can be distinguished (Fig. 687): (1) The upper part of the spleen is completely covered by the left lung; (2) the middle part corresponds to the costo-phrenic sinus; (3) the lower part extends over the lower pleural limit and projects down over the costal origin of the diaphragm. Its relations to the pleura and pleural cavity explain why wounds of the spleen can be accompanied by wounds of the lung and why abscess of the spleen may open through the diaphragm into the left pleural cavity.

It can also be seen how the limit of percussion is very narrow. The upper part is covered by the lung and thick muscles of the back. The part not covered by the lung applies itself to the left kidney and splenic flexure of colon whereby the percussion note may be modified, especially if fecal masses be in the colon or if the fundus of the stomach be filled with food. Abnormal enlargements of the spleen may be diagnosed by palpation as well as by percussion.

Relations.

Externally and above:
Peritoneum and left costal part of diaphragm;
Ninth, tenth, and eleventh ribs;
Costo-phrenic sinus;
Left lung and pleura;
(At birth) left lobe of liver;
Great muscles of back.

Internally:
Posterior surface of fundus of stomach;
Left kidney and capsule;
Tail of pancreas;
Sometimes vertebral column.

 Inferiorly:
Tail of pancreas sometimes;
Splenial flexure of colon;
Lig. phreno-colicum; saccus lienalis.

Fixation of Spleen and Peritoneal Relations.—The position of the spleen is secured by peritoneal folds which connect it with the diaphragm and neighboring organs.

The lig. phreno- lienale comes from the left crus of the diaphragm, and passes in the direction of the long axis of the spleen to its point of insertion, which is directly behind the inner border (margo intermedius). The ligament consists of firm connective tissue strands, and deserves the name suspensory ligament of the spleen (lig. suspensorium lienis).

The lig. gastro- lienale or gastro-splenic omentum connects the hilus of the spleen with the fundus of the stomach. It consists of an anterior layer formed of peritoneum of the greater sac, and a posterior layer which helps form the anterior wall of the lesser sac (Fig. 611). It only receives a strong consistency by the presence of the vasa gastrica brevia, which run in this fold from the hilus of the spleen to the stomach. The insertion of the ligament into the fundus of the stomach has no firm hold and can offer but little fixation to the spleen, but
rather serves to fasten the fundus of the stomach, which, in an empty state, needs support.

The lig. lienorenale (Fig. 611) is made of a posterior layer from the greater sac and an anterior layer which forms part of the posterior wall of the lesser sac. It contains the splenic vessels.

The lig. phreno-colicum (incorrectly costo-colic) contributes to the security of the spleen, although unconnected with it. It arises from the diaphragm opposite the anterior ends of the tenth and eleventh ribs, and passes below the spleen downward and inward to the splenic flexure of the colon and to the anterior surface of the descending colon. It forms a pocket, with its concavity directed upward and inward, the saccus lienalis, which, in the new-born, regularly receives the spleen. This ligament may also be called the sustentaculum lienis, supporter of the spleen. By the normal condition of the suspensory, and especially phreno-colic ligament, the spleen retains its position. Should the phreno-colic be relaxed then the spleen is displaced and its long axis becomes more vertical. In rare cases the normal spleen may sink deep into the abdominal cavity, even to the pelvis. This is called the "wandering spleen." It is liable to atrophy when the splenic artery suffers torsion. There are still two more inconstant ligaments, the lig. pancreatico-lienale and colico-lienale. The former is present when the tail of the pancreas does not reach the lower part of the inner surface of the spleen; then the visceral peritoneum from below and the lesser sac from above form a short band between these two organs, a part of the lig. lienorenale.

The lig. colico-lienale, when present, passes from the basal surface of the spleen downward and outward to the descending colon and joins the great omentum. It contributes to the formation of the saccus lienalis.

The ligaments, altogether, are the lig. gastro-lienale or gastro-splenic omentum; lig. phreno-lienale or suspensory ligament; lig. phreno-colicum or supporter of the spleen; lig. lienorenale, lig. pancreatico-lienale, and lig. colico-lienale, six in number.

Respiration exerts an influence upon the position of the spleen, and especially on the percussion limits. In inspiration it sinks somewhat, and its area of dulness is lessened from the overlapping of the lungs. Yet the respiratory motility of the spleen is much less than that of the liver, because the diaphragm exercises less influence over it than upon the liver. Hasse¹ states that in inspiration the spleen is compressed from above downward, and in expiration it passes upward and backward along the tenth rib. Pathological changes in the thoracic cavity, as effusions, will push the spleen down, or ascites and tumors in the abdominal cavity will push it up.

Vessels and Nerves of the Spleen.—The arteries are branches of the splenic; it divides about 3 cm. internal to the hilus into three or four branches which soon subdivide into twelve or fifteen twigs, which enter the gland. The splenic vein is about twice as large as the accompanying artery.

The lymphatic vessels are divided into a superficial and deep set. Sappey contends for a superficial set in man, which is proven in the horse, deer, and pig. The deeper lymphatic vessels follow the blood-vessels, one for each of the larger veins. At the hilus there are five or six trunks which empty into the glands situated there. In their farther course they follow the blood-vessels and unite with the lymphatics of the liver and stomach to form the thoracic duct.

The nerves come from the celiac plexus and right vagus; and accompany, sparingly, the splenic artery.

Structure.—The spleen is invested by two coats—an external serous and an internal fibro-elastic coat (tunica propria).

The external or serous coat is derived from the peritoneum; it is thin, smooth, and in the human subject intimately adherent to the fibro-elastic coat. It invests almost the entire organ, being reflected from it, at the hilus, on to the great end of the stomach, and at the upper end of the organ on to the diaphragm.

¹Arch. f. Anat. u. Phys., 1886, s. 208.
The **fibro-elastic coat** forms the framework of the spleen. It invests the exterior of the organ, and at the hilus is reflected inward upon the vessels in the form of vaginae or sheaths. From these sheaths, as well as from the inner surface of the fibro-elastic coat, numerous small fibrous bands, *trabeculae* (Fig. 688), are given off in all directions; these, uniting, constitute the areolar framework of the spleen. The framework of the spleen resembles, therefore, a sponge-like material, consisting of a number of small spaces or *areolæ*, formed by the trabeculae which are given off from the inner surface of the capsule, or from the sheaths prolonged inward on the blood-vessels. And in these spaces or areolæ is contained the **spleenic pulp**.

The proper coat, the sheaths of the vessels and the trabeculae, consist of a dense mesh of white and yellow elastic fibrous tissues, the latter considerably predominating. It is owing to the presence of this tissue that the spleen possesses a considerable amount of elasticity, which allows of the very great variations in size that it presents under certain circumstances. In addition to these constituents of this tunic, there is found in man a small amount of non-striped muscular fibre, and in some mammalia (*e.g.* dog, pig, and cat) a very considerable amount, so that the trabeculae appear to consist chiefly of muscular tissue. It is probably owing to this structure that the spleen exhibits, when acted upon by the galvanic current, faint traces of contractility.

The **proper substance of the spleen** or **spleen-pulp** is a soft mass of a dark reddish-brown color, resembling grumous blood. When examined, by means of a thin section, under a microscope, it is found to consist of a number of branching cells and an intercellular substance. The cells are connective-tissue corpuscles, and have been named the **sustentacular or supporting cells of the pulp**. The processes of these branching cells communicate with each other, thus forming a delicate reticulated tissue in the interior of the areolæ formed by the trabeculae of the capsule; so that each primary space may be considered to be divided into a number of smaller spaces by the junction of these processes of the branching corpuscles. These secondary spaces contain blood, in which, however, the white corpuscles are found to be in larger proportions than they are in ordinary blood. The sustentacular cells are either small uni-nucleated or larger multi-nucleated cells; they do not become deeply stained with carmine, like the cells of the Malpighian bodies, presently to be described (W. Müller), but like them they possess amoeboid movements (Cohnheim). In many of them may be seen deep red

![Fig. 688.—Transverse section of the spleen, showing the trabecular tissue and the splanic vein and its branches.](image-url)
or reddish-yellow granules of various sizes which present the characters of the haematin of the blood. Sometimes, also, unchanged blood-disks are seen included in these cells, but more frequently blood-disks are found which are altered both in form and color. In fact, blood-corpuscles in all stages of disintegration may be noticed to occur within them. Klein has recently pointed out that sometimes these cells in the young spleen contain a proliferating nucleus; that is to say, the nucleus is of large size, and presents a number of knob-like projections, as if small nuclei were budding from it by a process of gemmation. This observation is of importance, as it may explain one possible source of the colorless blood-corpuscles.

The interspaces or areolae formed by the framework of the spleen are thus filled by a delicate reticulum of branched connective-tissue corpuscles the interstices of which are occupied by blood, and in which the blood-vessels terminate in the manner now to be described.

**Blood-vessels of the Spleen.**—The splenic artery is remarkable for its large size in proportion to the size of the organ, and also for its tortuous course.

It divides into twelve to fifteen branches, which enter the hilus of the spleen and ramify throughout its substance (Fig. 689), receiving sheaths from an involution of the external fibrous tissue. Similar sheaths also invest the nerves and veins.

Each branch runs in the transverse axis of the organ from within outward, diminishing in size during its transit, and giving off in its passage smaller branches, some of which pass to the anterior, others to the posterior part. These ultimately leave the trabecular sheaths, and terminate in the proper substance of the spleen in small tufts or pencils of minute arterioles, which open into the interstices of the reticulum formed by the branched sustentacular cells. Each of the larger branches of the artery supplies chiefly that region of the organ in which the branch ramifies, having no anastomosis with the majority of the other branches.

The **arterioles**, supported by the minute trabeculae, traverse the pulp in all directions in bundles or penicilli of straight vessels. Their external coat, on leaving the trabecular sheaths, consists of ordinary connective tissue, but it gradually undergoes a transformation, becomes much thickened, and is converted into a lymphoid material.¹ This change is effected by the conversion of the connective tissue into a cystogenous tissue, the bundles of connective tissue becoming

¹ According to Klein, it is the sheath of the small vessel which undergoes this transformation, and forms a "solid mass of adenoid tissue which surrounds the vessel like a cylindrical sheath" (Atlas of Histology, p. 424).
looser and laxer, their fibrils more delicate, and containing in their interstices an abundance of lymph-corpuscles (W. Müller). This lymphoid material is supplied with blood by minute vessels derived from the artery with which they are in contact, and which terminates by breaking up into a network of capillary vessels.

The altered coat of the arterioles, consisting of lymphoid tissue, presents here and there thickenings of a spheroidal shape, the Malpighian bodies of the spleen. These bodies vary in size from about the \( \frac{1}{10} \) of an inch to the \( \frac{1}{27} \) of an inch in diameter. They are merely local expansions or hyperplasic of the lymphoid tissue of which the external coat of the smaller arteries of the spleen is formed. They are most frequently found surrounding the arteriole, which thus seems to tunnel them, but occasionally they grow from one side of the vessel only, and present the appearance of a sessile bud growing from the arterial wall. Klein, however, denies this, and says it is incorrect to describe the Malpighian bodies as isolated masses of adenoid tissue, but that they are always formed around an artery, though there is generally a greater amount on one side than the other, and that, therefore, in transverse sections the artery in the majority of cases is found in an eccentric position. These bodies are visible to the naked eye on the surface of a fresh section of the organ, appearing as minute dots of semi-opaque whitish color in the dark substance of the pulp. In minute structure they resemble the adenoid tissue of lymphatic glands, consisting of a delicate reticulum in the meshes of which lie ordinary lymphoid cells (Fig. 690).

The reticulum of the tissue is made up of extremely delicate fibrils, and is comparatively open in the centre of the corpuscle, becoming closer at the periphery of the body. The cells which it encloses, like the supporting cells of the pulp, are possessed of amœboid move-

![Fig. 600.—Artery from a dog's spleen, showing Malpighian corpuscles. (Kölliker.)](image-url)

![Fig. 601.—Section of spleen, showing the termination of the small blood-vessels.](image-url)

ments, but when treated with carmine become deeply stained, and can thus easily be recognized from those of the pulp.

The arterioles terminate in capillaries, which traverse the pulp in all directions;
their walls become much attenuated, lose their tubular character, and the cells of the lymphoid tissue of which they are composed become altered, presenting a branched appearance and acquiring processes which are directly connected with the processes of the sustentacular cells of the pulp (Fig. 691). In this manner the capillary vessels terminate, and the blood flowing through them finds its way into the interstices of the reticulated tissue formed by the branched connective-tissue corpuscles of the splenic pulp. Thus the blood passing through the spleen is brought into intimate relation with the elements of the pulp, and no doubt undergoes important changes.

After these changes have taken place the blood is collected from the interstices of the tissue by the rootlets of the veins, which commence much in the same way as the arteries terminate. Where a vein is about to commence the connective-tissue corpuscles of the pulp arrange themselves in rows in such a way as to form an elongated space or sinus. They become changed in shape, being elongated and spindle-shaped, and overlap each other at their extremities. They thus form a sort of endothelial lining of the path or sinus, which is the radicle of a vein. On the outer surface of these cells are seen delicate transverse lines or markings which are due to minute elastic fibrillae arranged in a circular manner around the sinus. Thus the channel obtains a continuous external investment, and gradually becomes converted into a small vein, which after a time presents a coat of ordinary connective tissue, lined by a layer of fusiform epithelial cells which are continuous with the supporting cells of the pulp. The smaller veins unite to form larger ones which do not accompany the arteries, but soon enter the trabecular sheaths of the capsule, and by their junction form from four to six branches which emerge from the hilum and, uniting, form the splenic vein, the largest radicle of the vena porta.

The veins are remarkable for their numerous anastomoses, while the arteries hardly anastomose at all.

The lymphatics originate in two ways—i. e. a trabecular set and a perivascular set. The former run on the trabeculae and empty into the superficial network of the capsule. The perivascular is the deep set, rising in the lymphoid tissue surrounding the arteries and forming Malpighian corpuscles. At first they have no walls. They are seen to run with an artery in pairs and singly with each larger vein, forming many anastomoses. Both sets join at the hilus (see page 1077).

**Surface Form.**—The spleen is situated under cover of the ribs of the left side, being separated from them by the Diaphragm, and above by a small portion of the lower margin of the left lung. Its position corresponds to the ninth, tenth, and eleventh ribs. It is placed very obliquely. "It is oblique in two directions, viz. from above downward and outward, and also from above downward and forward" (Cunningham). "Its highest and lowest points are on a level respectively with the ninth dorsal and first lumbar spines; its inner end is distant about an inch and a half from the median plane of the body, and its outer end about reaches the midaxillary line." (Quain).

**Surgical Anatomy.**—Injury of the spleen is less common than that of the liver, on account of its protected situation and connections. It may be ruptured by direct or indirect violence, torn by a broken rib, or injured by a punctured or gunshot wound. When the organ is enlarged the chance of rupture is increased. The great risk is hemorrhage, owing to the great vascularity of the organ, and the absence of a proper system of capillaries. The injury is not, however, necessarily fatal, and this would appear to be due in a great measure to the contractile power of its capsule, which narrows the wound and prevents the escape of blood. In cases where the diagnosis is clear and the symptoms indicate danger to life laparotomy must be performed; and if the hemorrhage cannot be stayed by ordinary surgical methods the spleen must be removed. The spleen may become displaced, producing great pain from stretching of the vessels and nerves, and this may require removal of the organ. The spleen may become enormously enlarged in certain diseased conditions, such as ague, syphilis, valvular disease of the heart, or without any obtainable history of previous disease. It may also become enlarged in lymphadenoma as a part of a general blood-disease. In these cases the tumor may sometimes fill the abdomen and extend into the pelvis, and may be mistaken for ovarian or uterine disease.

The spleen is sometimes the seat of cystic tumors, especially hydatids, and of abscess. These cases require treatment by incision and drainage; and in abscess great care must be taken if there are no adhesions between the spleen and abdominal cavity, to prevent the escape of any of the pus into the peritoneal cavity. If possible, the operation should be performed in two
THE ORGANS OF DIGESTION.

stages, as in abscess of the liver. Sarcoma and carcinoma are occasionally found in the spleen, but very rarely as a primary disease.

Extirpation of the spleen has been performed for wounds or injuries, in floating spleen, in simple hypertrophy, and in leukaemic enlargement; but in these latter cases the operation is now regarded as unjustifiable, as every case in which it has been performed has terminated fatally. The incision is best made in the left semilunar line: the spleen is isolated from its surroundings, and the pedicle transfixed and ligatured in two portions, before the tumor is turned out of the abdominal cavity, if this is possible, so as to avoid any traction on the pedicle, which may cause tearing of the splenic vein. In applying the ligature care must be taken not to include the tail of the pancreas, and in lifting out the organ to avoid rupturing the capsule.
THE THORAX.

The Thorax is a cone-shaped cavity containing and protecting the heart, enclosed in its membranous bag, the pericardium, and the lungs, invested by the pleura. Its shape and boundaries have already been described (see page 288).

The Cavity of the Thorax.—The size of the cavity of the thorax does not correspond with its apparent size externally, because (1) the space enclosed by the lower ribs is occupied by some of the abdominal viscera, and (2) the cavity extends above the first rib into the neck. The size of the cavity of the thorax is constantly varying during life with the movements of the ribs and Diaphragm and with the degree of distension of the abdominal viscera. From the collapsed state of the lungs in the dead body it would appear as if the viscera only partly filled the cavity of the thorax, but during life there is no vacant space, that which is seen after death being filled up by the expanded lungs.

The Upper Opening of the Thorax.—The parts which pass through the upper opening of the thorax are, from before backward in the middle line, the Sternohyoid and Sterno-thyroid muscles, the remains of the thymus gland, the trachea, oesophagus, thoracic duct, and the Longus colli muscle of each side; at the sides, the innominate artery, the left common carotid and left subclavian arteries, the internal mammary and superior intercostal arteries, the right and left innominate veins, and the inferior thyroid veins, the pneumogastric, cardiac, phrenic, and sympathetic nerves, the anterior branch of the first dorsal nerve, and the recurrent laryngeal nerve of the left side. The apex of each lung, covered by the pleura, also projects through this aperture, a little above the margin of the first rib.

The Lower Opening of the Thorax is wider transversely than from before backward. It slopes obliquely downward and backward, so that the cavity of the thorax is much deeper behind than in front. The Diaphragm (see page 444) closes in the opening, forming the floor of the thorax. The floor is flatter at the centre than at the sides, and is higher on the right side than on the left, corresponding in the dead body to the upper border of the fifth costal cartilage on the former, and to the corresponding part of the sixth costal cartilage on the latter. From the highest point on each side the floor slopes suddenly downward to the attachment of the Diaphragm to the ribs; this is more marked behind than in front, so that only a narrow space is left between it and the wall of the thorax.

For measurements of the thorax see page 1099.

THE PERICARDIUM.

The Pericardium (Figs. 692, 693) is a conical membranous sac in which the heart and the commencement of the great vessels are contained. It is placed behind the sternum and the cartilages of the third, fourth, fifth, sixth, and seventh ribs of the left side, in the interval between the pleura.

Its apex is directed upward, and surrounds the great vessels about two inches above their origin from the base of the heart. Its base is attached to the central tendon and part of the adjoining muscular structure of the Diaphragm, extending a little farther to the left than to the right side. In front it is separated from the sternum by the remains of the thymus gland above and a little loose areolar tissue below, and is covered by the margins of the lungs, especially the left. Behind, it rests upon the bronchi, the oesophagus, and the descending aorta. Laterally, it is covered by the pleura, the phrenic nerve with its accompanying vessels descending between the two membranes on either side.
Structure of the Pericardium.—The pericardium is a fibro-serous membrane, and consists, therefore, of two layers, an external fibrous and an internal serous.

The fibrous layer is a strong, dense membrane. Above, it surrounds the great vessels arising from the base of the heart, on which it is continued in the form of tubular prolongations which are gradually lost upon their external coat, the strongest being that which encloses the aorta. The pericardium may be traced over these vessels, to become continuous with the deep layer of the cervical fascia. On each side of the ascending aorta it sends upward a diverticulum: the one on the left side, somewhat conical in shape, passes upward and outward, between the arch of the aorta and the left pulmonary artery, as far as the ductus arteriosus, where it terminates in a caecal extremity, which is attached by loose connective tissue to the obliterated duct (Fig. 692). The one on the right side passes upward and to the right, between the ascending aorta and vena cava superior, and also terminates in a caecal extremity. Below, the fibrous layer is attached to the central tendon of the Diaphragm, and on the left side to its muscular fibres. Anteriorly the pericardium is connected to the sternum by two variable bands of fascia, the superior and inferior sterno-pericardial ligaments of Luschka.

The vessels receiving fibrous prolongations are the aorta, the superior vena cava, the right and left pulmonary arteries, and the four pulmonary veins. As the inferior vena cava enters the pericardium, it receives no covering from the fibrous layer.

---

Fig. 692—Pericardium, from in front. The sac has been distended with plaster. (From a preparation in the Museum of the Royal College of Surgeons.)
The serous layer invests the heart, and is then reflected on the inner surface of the pericardium. It consists, therefore, of a visceral and parietal portion. The former invests the surface of the heart and the commencement of the great vessels to the extent of one inch and a half from their origin; from these it is reflected upon the inner surface of the fibrous layer. The serous membrane encloses the aorta and pulmonary artery in a single tube; hence between these vessels and the auricles posteriorly is a passage, the transverse pericardial sinus; but it only partially covers the superior and inferior vena cava and the four pul-

monary veins. Its inner surface is smooth and glistening, and secretes a thin fluid which serves to facilitate the movements of the heart.

Arteries of the Pericardium.—These are derived from the internal mammary and its musculo-phrenic branch and from the descending thoracic aorta.

Nerves of the Pericardium.—These are branches from the vagus, the phrenic, and the sympathetic.

The Vestigial Fold of the Pericardium.—When the pericardium is opened there is seen lying between the left pulmonary artery and subjacent pulmonary vein a triangular fold (vestigial fold of Marshall) of the serous layer, which encloses between its layers the remains, a fibrous cord, of the left superior vena cava. This cord may sometimes be traced upward to the left superior intercostal vein.
Surgical Anatomy.—Paracentesis of the pericardium is sometimes required in cases of effusion into its cavity. The operation is best performed in the fifth intercostal space, one inch to the left of the sternum. The operation has been performed, however, in the fourth, sixth, and seventh spaces, and also on the right side of the sternum.

THE HEART.

The Heart is a hollow muscular organ, of a conical form, placed between the lungs and enclosed in the cavity of the pericardium.

Position.—The heart is placed obliquely in the chest: the broad attached end, or base, is directed upward, backward, and to the right, and corresponds to the interval between the fifth and ninth dorsal vertebrae—that is, it lies opposite the sixth, seventh, and eighth vertebrae; the apex is directed downward, forward, and to the left, and corresponds to the space between the cartilage of the fifth and sixth ribs, three-quarters of an inch to the inner side and an inch and a half below the left nipple. The heart is placed behind the lower two-thirds of the sternum, and projects farther into the left than into the right cavity of the chest, extending from the median line about three inches in the former direction, and only one and a half in the latter. The anterior surface of the heart is round and convex, directed upward and forward, and formed chiefly by the right ventricle and part of the left. Its posterior surface is flattened and rests upon the Diaphragm, and is formed chiefly by the left ventricle. The right border is long, thin, and sharp; the left border short, but thick and round.
Size.—The heart in the adult measures five inches in length, three inches and a half in breadth in the broadest part, and two inches and a half in thickness. The prevalent weight, in the male, varies from ten to twelve ounces; in the female, from eight to ten: its proportions to the body being as 1 to 169 in males, 1 to 149 in females. The heart continues increasing in weight, and also in length, breadth, and thickness, up to an advanced period of life: this increase is more marked in men than in women.

Component Parts.—The heart is subdivided by a longitudinal muscular septum into two lateral halves, which are named respectively, from their position, right and left; and a transverse constriction subdivides each half of the organ into two cavities, the upper cavity on each side being called the auricle, the lower the ventricle. The right is the venous side of the heart, receiving into its auricle the dark venous blood from the entire body, by the superior and inferior vena cava and coronary sinus. From the right auricle the blood passes into the right ventricle, and from the right ventricle, through the pulmonary artery, into the lungs. The blood, arterialized by its passage through the lungs, is returned to the left side of the heart by the pulmonary veins, which open into the left auricle; from the left auricle the blood passes into the left ventricle, and from the left ventricle is distributed, by the aorta and its subdivisions, through the entire body. This constitutes the circulation of the blood in the adult.

The great transverse groove separates the auricles from the ventricles, and is called the auriculo-ventricular groove. It is deficient, in front, from being crossed by the root of the pulmonary artery. The two ventricles are also separated from each other on the surface by two longitudinal furrows, the interventricular grooves, which are situated one on the anterior, the other on the posterior surface; these extend from the base of the ventricle to a little to the right of the apex of the organ, where they are continuous, the former being situated nearer to the left border of the heart, and the latter to the right. It follows, therefore, that the right ventricle forms the greater portion of the anterior surface of the heart, and the left ventricle more of its posterior surface, while the apex is made up entirely of the left ventri-
cle. The grooves contain the coronary arteries, cardiac veins, lymphatics, nerves, and fat, all covered by the visceral layer of the serous pericardium.

Each of these cavities should now be separately examined.

To examine the interior of the right auricle, an incision should be made along its right border from the entrance of the superior vena cava to that of the inferior. A second cut is to be made from the centre of this first incision to the tip of the auricular appendix, and the flaps raised.

The **Right Auricle** is a little larger than the left, its walls somewhat thinner, measuring about one line, and its cavity is capable of containing about two ounces. It consists of two parts—a principal cavity, or **sinus venosus** or atrium, and an **appendix auriculi**.

The **sinus** is the large quadrangular cavity placed between the two venae cavae; its walls are extremely thin; it is connected below with the right ventricle, and internally with the left auricle, being free in the rest of its extent.

The **appendix auriculi**, so called from its fancied resemblance to a dog's ear, is a small conical muscular pouch the margins of which present a dentated edge. It projects from the sinus forward and to the left side, overlapping the root of the aorta.

The internal surface of the right auricle is smooth, except in the appendix and adjacent part of the anterior or right wall of the sinus venosus, where it is thrown into parallel ridges (**musculi pectinati**).

It presents the following parts for examination:

The **superior vena cava** returns the blood from the upper half of the body, and opens into the upper and back part of the auricle, the direction of its orifice being downward and forward.

The **inferior vena cava**, larger than the superior, returns the blood from the lower half of the body, and opens into the lowest part of the auricle near the septum, the direction of its orifice being upward and inward. The direction of a current of blood through the superior vena cava would consequently be toward the auriculo-ventricular orifice, whilst the direction of the blood through the inferior cava would be toward the auricular septum. This is the normal direction of the two currents in fetal life.

The **tuberculum Loweri** is a small projection on the right wall of the auricle, between the two vena cavae. It is most distinct in the hearts of quadrupeds; in man it is scarcely visible. It was supposed by Lower to direct the blood from the superior cava toward the auriculo-ventricular opening.

The **coronary sinus** opens into the auricle, between the inferior vena cava and the auriculo-ventricular opening. It returns the blood from the substance of the heart, and is protected by a semicircular fold of the lining membrane of the auricle, the **coronary valve** (*valve of Thebesius*). The sinus, before entering the auricle, is considerably dilated—nearly to the size of the end of the little finger. Its wall is partly muscular, and at its junction with the great coronary vein is somewhat constricted and furnished with a valve consisting of two unequal segments.

The **foramina Thebesii** are numerous minute apertures, the mouths of small veins (*venae cordis minima*), which open on various parts of the inner surface of the auricle. They return the blood directly from the muscular substance of the
heart. Some of these foramina are minute depressions in the walls of the heart, presenting a closed extremity.

The **auriculo-ventricular opening** is the large oval aperture of communication between the auricle and the ventricle, to be presently described.

The **Eustachian valve** is situated between the anterior margin of the inferior vena cava and the auriculo-ventricular orifice. It is semilunar in form, its convex margin being attached to the wall of the vein; its concave margin, which is free, terminating in two cornua, of which the left is attached to the anterior edge of the annulus ovalis, the right being lost on the wall of the auricle. The valve is formed by a duplicature of the lining membrane of the auricle containing a few muscular fibres.

*In the fetus* this valve is of large size, and serves to direct the blood from the inferior vena cava, through the foramen ovale, into the left auricle.

*In the adult* it is occasionally persistent, and may assist in preventing the reflux of blood into the inferior vena cava; more commonly it is small, and its free margin presents a cribriform or filamentous appearance; occasionally it is altogether wanting.

The **coronary valve** (valve of Thebesius) is a semicircular fold of the lining membrane of the auricle, protecting the orifice of the coronary sinus. It prevents the regurgitation of blood into the sinus during the contraction of the auricle. This valve is occasionally double.

The **fossa ovalis** is an oval depression corresponding to the situation of the foramen ovale in the fetus. It is situated at the lower part of the septum auriculatum, above and to the left of the orifice of the inferior vena cava.

The **annulus ovalis** is the prominent oval margin of the foramen ovale. It is most distinct above and at the sides; below, it is deficient. A small slit-like valvular opening is occasionally found, at the upper margin of the fossa ovalis, which leads upward beneath the annulus into the left auricle, and is the remains of the aperture between the two auricles in the fetus.

The **musculi pectinati** are small, prominent muscular columns which run across the inner surface of the appendix auriculae and adjoining portion of the wall of the sinus. Posteriorly, they join a vertical ridge, the crista terminalis of His. They are called pectinati from their fancied resemblance to the teeth of a comb.

The **Right Ventricle** is triangular in form, and extends from the right auricle to the apex of the heart. Its anterior or upper surface is rounded and convex, and forms the larger part of the front of the heart. Its under surface is flattened, rests upon the Diaphragm, and forms only a small part of the back of the heart. Its posterior wall is formed by the partition between the two ventricles, the septum ventriculorum, the surface of which is convex and bulges into the cavity of the right ventricle. Its upper and left angle is prolonged into a conical pouch, the infundibulum or conus arteriosus, from which the pulmonary artery arises. The walls of the right ventricle are thinner than those of the left, the proportion between them being as 1 to 3. The wall is thickest at the base, and gradually becomes thinner toward the apex. The cavity, which equals that of the left ventricle, is capable of containing about three fluidounces.¹

To examine the interior of the right ventricle, an incision should be made a little to the right of the anterior interventricular groove from the pulmonary artery to the apex of the heart, and should be carried up from thence a little to the right of the posterior interventricular groove, as far as the auriculo-ventricular opening.

The following parts present themselves for examination:

- **Openings**
  - Auriculo-ventricular.
  - Opening of the pulmonary artery.

- **Valves**
  - Tricuspid.
  - Semilunar.

¹ Morrant Baker says that "taking the means of various estimates, it may be inferred that each ventricle is able to contain four to six ounces of blood" (Kirke's Physiology, 10th edition, p. 156).
And a muscular and tendinous apparatus connected with the tricuspid valve:

The auriculo-ventricular orifice is the large oval aperture of communication between the auricle and ventricle. It is situated at the base of the ventricle, near the right border of the heart. The opening is about an inch in diameter,\(^1\) oval from side to side, surrounded by a fibrous ring, covered by the lining membrane of the heart, and rather larger than the corresponding aperture on the left side. It is guarded by the tricuspid valve.

The opening of the pulmonary artery is circular in form, and situated at the summit of the conus arteriosus, close to the septum ventriculorum. It is placed on the left side of the auriculo-ventricular opening, upon the anterior aspect of the heart, and, when viewed from above, on cross-section, the aortic opening is seen intervening. Its orifice is guarded by the pulmonary semilunar valves.

The tricuspid valve consists of three segments of a triangular or trapezoidal shape, formed by a duplication of the lining membrane of the heart, reflected on both sides of a layer of fibrous tissue, which contains, according to Kurschner and Senae, muscular fibres. These segments are connected by their bases to the auriculo-ventricular orifice, and to one another, so as to form a continuous annular membrane which is attached round the margin of the auriculo-ventricular opening, their free margins and ventricular surfaces affording attachment to a number of delicate tendinous cords, the chordae tendineae. The largest and most movable segment, placed toward the left and anterior side of the auriculo-ventricular opening, is directed downward between that opening and the infundibulum (left or infundibular flap). Another segment corresponds to the front and right of the ventricle (right flap), and a third to its posterior wall (posterior or septal flap). The central part of each segment is thick and strong; the lateral margins are thin and indented. The chordae tendineae are connected with the segments of the valve in the following manner: 1. Three or four reach the attached margin of each segment, where they are continuous with the auriculo-ventricular tendinous ring. 2. Others, four to six in number, are attached to the central thickened part of each segment. 3. The most numerous and finest are connected with the marginal portion of each segment.

The columnae carneae are muscular columns which project from the inner surface, excepting near the opening of the pulmonary artery, where the wall becomes smooth. They may be classified into three sets: The first merely form prominent ridges; the second set (trabeculae) are attached by their two extremities only; whilst the third set (musculi papillares) are attached by one extremity to the wall of the heart, the opposite extremity giving attachment to the chordae tendineae. There are two papillary muscles, anterior and posterior. The chordae tendineae of the former go to the left and right segments. Those of the latter, which is often replaced by two or three smaller ones, pass to the right and septal segments. There is still another set of chordae which arise directly from the septum and pass to the septal and left segments.

The semilunar valves, three in number,\(^2\) guard the orifice of the pulmonary artery. They consist of three semicircular folds, two anterior (right and left) and one posterior, formed by a fibrous membrane, covered above by the inner coat of the artery and below by a reflection of the endocardium. They are attached by

---

1 In the Pathological Transactions, vol. vi. p. 119, Dr. Pesock has given some careful researches upon the weight and dimensions of the heart in health and disease. He states, as the result of his investigations, that in the healthy adult heart the right auriculo-ventricular aperture has a mean circumference of 54.4 lines, or 4\(\frac{3}{4}\) inches; the left auriculo-ventricular aperture, a mean circumference of 44.3 lines, or 3\(\frac{3}{4}\) inches; the pulmonic orifice, of 40 lines, or 3\(\frac{3}{4}\) inches; and the aortic orifice, of 35.5 lines, or 3\(\frac{3}{4}\) inches; but the dimensions of the orifices varied greatly in different cases, the auriculo-ventricular aperture having a range of from 45 to 60 lines, and the others in the same proportion.

2 The pulmonary semilunar valves have been found to be two in number, instead of three (Dr. Hand, of St. Paul, Minn., in the North-Western Med. and Surg. Jour., July, 1873), and the same variation is more frequently noticed in the aortic semilunar valves.
their convex margins to the wall of the artery at its junction with the ventricle, the straight border being free, and directed somewhat upward in the lumen of the vessel. The free margin of each is somewhat thicker than the rest of the valve, is strengthened by a bundle of tendinous fibres, and presents at its middle a small projecting thickened nodule called corpus Arantii. From this nodule tendinous fibres radiate through the valve to its attached margin, and these fibres form a constituent part of its substance throughout its whole extent, excepting two narrow lunated portions (lunulae) placed on each side of the nodule immediately behind the free margin; here the valve is thin and formed merely by the lining membrane. During the passage of the blood along the pulmonary artery these valves are pressed against the sides of the cylinder and the course of the blood along the tube is uninterrupted; but during the ventricular diastole, when the current of blood along the pulmonary artery is checked and partly thrown back by its elastic walls, these valves become immediately expanded and effectually close the entrance of the tube. When the valves are closed the lunated portions of each are brought into contact with one another by their opposed surfaces, the three corpora Arantii filling up the small triangular space that would be otherwise left by the approximation of the three semilunar valves.

Between the semilunar valves and the commencement of the pulmonary artery are three pouches or dilatations, one behind each valve. These are the pulmonary sinuses (sinuses of Valsalva). Similar sinuses exist between the semilunar valves and the commencement of the aorta; they are larger than the pulmonary sinuses. The blood, in its regurgitation toward the heart, finds its way into these sinuses, and so shuts down the valve-flaps.

In order to examine the interior of the left auricle, make an incision on the posterior surface of the auricle from the pulmonary veins on one side to those on the other, the incision being carried a little way into the vessels. Make another incision from the middle of the horizontal one to the appendix.

The Left Auricle is rather smaller than the right; its walls thicker, measuring about one line and a half; it consists, like the right, of two parts, a principal cavity, atrium or sinus and an appendix auricula.

The sinus is cuboidal in form, and concealed in front by the pulmonary artery and aorta; internally, it is separated from the right auricle by the septum auriculorum: behind, it receives on each side two pulmonary veins, being free in the rest of its extent.

The appendix auriculae is somewhat constricted at its junction with the auricle; it is longer, narrower, and more curved than that of the right side, and its margins are more deeply indented, presenting a kind of foliated appearance. Its direction is forward and toward the right side, overlapping the root of the pulmonary artery.

Within the auricle the following parts present themselves for examination:

The openings of the four pulmonary veins.
Auriculo-ventricular opening.
Musculi pectinati.

The pulmonary veins, four in number, open, two into the right, and two into the left side of the auricle. The two left veins frequently terminate by a common opening. They are not provided with valves.

The auriculo-ventricular opening is the large oval aperture of communication between the auricle and ventricle. It is rather smaller than the corresponding opening on the opposite side (see note, page 1080).

1 In former editions, as well as in other text-books on anatomy, these little nodules have been described as fibro-cartilaginous in structure. At my request, Dr. Le Cronier Lancaster, Demonstrator of Anatomy at St. George's Hospital, has investigated this subject, and reports that the "corpora Arantii" appear to consist of bundles of interlacing connective-tissue fibres with branched connective-tissue cells, and some few elastic fibres. Occasionally a rounded cell, with indistinct capsule, resembling a cartilage-cell was seen; but there were not many of them. At the free edge of the corpus the structure is denser, there being a larger proportion of fibres to cells than in the central portion. He thinks the structure of the corpus should be put down as fibrous and not fibro-cartilaginous.
The musculi pectinati are fewer in number and smaller than on the right side; they are confined to the inner surface of the appendix.

On the inner surface of the septum auriculorum may be seen a lunated impression bounded below by a crescentic ridge the concavity of which is turned upward. The depression is just above the fossa ovalis in the right auricle.

To examine the interior of the left ventricle, make an incision a little to the left of the anterior interventricular groove from the base to the apex of the heart, and carry it up, from thence, a little to the left of the posterior interventricular groove, nearly as far as the auriculo-ventricular groove.

The **Left Ventricle** is longer and more conical in shape than the right ventricle. It forms a small part of the left side of the anterior surface of the heart, and a considerable part of its posterior surface. It also forms the apex of the heart by its projection beyond the right ventricle. Its walls are much thicker than those of the right side, the proportion being as 3 to 1. They are also thickest in the broadest part of the ventricle, becoming gradually thinner toward the base, and also toward the apex, which is the thinnest part.

The following parts present themselves for examination within the ventricle:

- **Openings**
  - Auriculo-ventricular
  - Aortic

- **Valves**
  - Mitral
  - Semilunar
  - Columnae carneae

The **auriculo-ventricular opening** is placed below and to the left of the aortic orifice. It is a little smaller than the corresponding aperture of the opposite side, and, like it, is broader in the transverse than in the antero-posterior diameter. It is surrounded by a dense fibrous ring, covered by the lining membrane of the heart, and guarded by the mitral valves.

The **aortic opening** is a circular aperture in front and to the right side of the auriculo-ventricular, from which it is separated by one of the segments of the mitral valve. Its orifice is guarded by the semilunar valves.
The mitral or bicuspid valve is attached to the circumference of the auriculo-ventricular orifice in the same way that the tricuspid valve is on the opposite side. It is formed by fibrous membrane covered on both surfaces by endocardium, and contains a few muscular fibres. It is large in size, thicker, and altogether stronger than the tricuspid, and consists of two segments of unequal size. The large segment is placed in front and to the right, between the auriculo-ventricular and aortic orifices. Two smaller segments are usually found at the angles of junction of the larger. Similar segments are less constantly found between the main ones of the tricuspid valve. The mitral valve-flaps are furnished with chordae tendineae, the mode of attachment of which is precisely similar to that of those on the right side, but they are thicker, stronger, and less numerous.

The semilunar valves surround the orifice of the aorta; two are posterior (right and left), and one anterior; they are similar in structure and mode of attachment to the pulmonary valves. They are, however, larger, thicker, and stronger, the lunulae are more distinct, and the corpora Arantii larger and more prominent. Between each valve and the cylinder of the aorta is a deep depression, the sinus aortici (sinuses of Valsalva); they are larger than those of the root of the pulmonary artery. The right coronary artery arises from the anterior; the left from the left posterior.

The columnae carnea admit of a subdivision into three sets, like those upon the right side, but they are smaller, more numerous, and present a dense interlace-ment, especially at the apex and upon the posterior wall. Those attached by one extremity only, the musculi papillares, are two in number, being connected one to the anterior, the other to the posterior wall; they are of large size, and terminate by free rounded extremities from which the chordae tendineae arise.

The septum between the two ventricles is thick, especially below (Fig. 697).
At its upper part it suddenly tapers off and loses its muscular fibres, consisting only of fibrous tissue covered by two layers of endocardium, and on the right side it is also, during diastole, in contact with the septal flap of the tricuspid valve. It continues upward, and forms the septum between the aortic vestibule and the right auricle. It is derived from the lower part of the aortic septum of the focus, and an abnormal communication may exist at this part owing to defective development. The *aortic vestibule* (Sibson) is a small portion of the ventricular cavity immediately under the root of the aorta.

The *Endocardium* is a thin membrane which lines the internal surface of the heart; it assists in forming the valves by its reduplications, and is continuous with the lining membrane of the great blood-vessels. It is a smooth, transparent membrane, giving to the inner surface of the heart its glistening appearance. It is more opaque on the left than on the right side of the heart, thicker in the auricles than in the ventricles, and thickest in the left auricle. It is thin on the musculi pectinati and on the columnae carneae, but thicker on the smooth part of the auricular and ventricular walls and on the tips of the musculi papillares.

**Structure.**—The heart consists of muscular fibres and of fibrous rings which serve for their attachment.

The *fibrous rings* surround the auriculo-ventricular and arterial orifices: they are stronger upon the left than on the right side of the heart. The auriculo-ventricular rings serve for the attachment of the muscular fibres of the auricles and ventricles, and also for the mitral and tricuspid valves; the ring on the left side is closely connected by its right margin with the aortic arterial ring. Between these and the right auriculo-ventricular ring is a mass of fibrous tissue, and in some of the larger animals, as the ox and elephant, a nodule of bone.

The fibrous rings surrounding the arterial orifices serve for the attachment of the great vessels and semilunar valves. Each ring receives, by its ventricular margin, the attachment of the muscular fibres of the ventricles; its opposite margin presents three deep semicircular notches, within which the middle coat of the artery (which presents three convex semicircular segments) is firmly fixed, the attachment of the artery to its fibrous ring being strengthened by the thin cellular coat and serous membrane externally and by the endocardium within. It is opposite the margins of these semicircular notches, in the arterial rings, that the endocardium by its reduplication, forms the semilunar valves, the fibrous structure of the ring being continued into each of the segments of the valve at this part. The middle coat of the artery in this situation is thin, and the sides of the vessel are dilated to form the sinuses of Valsalva.

The muscular *structure of the heart* (myocardium) consists of bands of fibres which present an exceedingly intricate interlacement. They are of a deep red color and marked with transverse striae *(page 65).*

The muscular fibres of the heart admit of a subdivision into two kinds, those of the auricles and those of the ventricles, which are quite independent of one another.

**Fibres of the Auricles.**—These are disposed in two layers—a superficial layer common to both cavities, and a deep layer proper to each. The superficial fibres are more distinct on the anterior surface of the auricles, across the bases of which they run in a transverse direction, forming a thin, but incomplete layer. Some of these fibres pass into the septum auricularum. The internal or deep fibres proper to each auricle consist of two sets, looped and annular fibres. The looped fibres pass upward over each auricle, being attached by two extremities to the corresponding auriculo-ventricular rings in front and behind. The annular fibres surround the whole extent of the appendices auricularum, and are continued upon the walls of the venæ cavae and coronary sinus on the right side, and upon the pulmonary veins on the left side, at their connection with the heart. In the appendices they interface with the longitudinal fibres.

**Fibres of the Ventricles.**—These are arranged in an exceedingly complex manner, and the accounts given by various anatomists differ considerably. This is probably due partly to the fact that the various layers of muscular fibres of which the
THE HEART.

1095

heart is said to be composed are not independent, but their fibres are interlaced to a considerable extent, and therefore any separation into layers must be to a great extent artificial; and also no doubt partly due to the fact, pointed out by Henle, that there are varieties in the arrangement due to individual differences. If the epicardium (visceral layer of pericardium) and the subjacent fat is removed from a heart which has been subjected to prolonged boiling, so as to dissolve the connective tissues, the superficial fibres of the ventricles will be exposed. They will be seen to commence at the base of the heart, where they are attached to the tendinous rings around the orifices, and to pass obliquely downward toward the apex, with a direction from right to left. At the apex the fibres turn suddenly inward, forming what is called the vortex, into the interior of the left ventricle. On the back of the heart it will be seen that the fibres pass continuously from one ventricle to the other over the interventricular groove; and the same thing will be noticed on the front of the heart at the upper and lower end of the anterior interventricular groove, but in the middle portion of this groove the fibres passing from one ventricle to the other are interrupted by fibres emerging from the septum along the groove; many of the superficial fibres pass in also at this groove to the septum. The vortex is produced, as stated above, by the sudden turning inward of the superficial fibres in a peculiar spiral manner into the interior of the left ventricle. Those fibres which descended on the posterior surface of the heart enter, at the vortex, the left ventricle, and, ascending, form part of the inner layer of muscular fibres lining this cavity and the right (posterior) musculus papillaris; those fibres which descend on the front of the heart, and which pass to the apex, also pass, at the vortex, into the interior of the ventricle, where they also form the remainder of the innermost layer of the ventricle and the left (anterior) musculus papillaris. The fibres forming the inner layer of the wall of the ventricle ascend to be attached to the fibrous rings around the orifices.

By dissection these superficial fibres may be removed as a thin stratum, and it will then be found that the ventricles are made up of oblique fibres superimposed in layers one on the top of another, and assuming gradually a less oblique direction as they pass to the middle of the thickness of the ventricular wall, so that in the centre of the wall the fibres are transverse. Internal to this central transverse layer the fibres become oblique again, but in the opposite direction to the external ones. This division into distinct layers is, however, to a great extent artificial, as the fibres pass across from one layer to another, and have therefore to be divided in the dissection, and the change in the direction of the fibres is very gradual. These oblique fibres commence above at the fibrous rings at the base of the heart, and, descending toward the apex, they enter the septum near its lower end. In the septum the fibres which form the left ventricle may be traced in three directions: 1. Some pass upward to be attached to the central fibro-cartilage. 2. Others pass through the septum to become continuous with the fibres of the right ventricle. 3. The remainder pass through the septum to encircle the ventricle as annular fibres. Of the fibres of the right ventricle, some on entering the septum pass upward to be attached to the central fibro-cartilage; some, entering the septum from behind, pass forward to become continuous with the fibres on the anterior surface of the left ventricle; and others, entering in front, pass backward to join the fibres on the posterior wall of the left ventricle. The septum therefore consists of three varieties of fibres—viz. annular fibres, special to the left ventricle; ascending fibres, derived from both ventricles and ascending through the septum to the central fibro-cartilage; and decussating fibres, derived from the anterior wall of one ventricle and passing to the posterior wall of the other ventricle, or from the posterior wall of the right ventricle and passing to the anterior wall of the left. In addition to these fibres there are a considerable number which appear to encircle both ventricles and which pass across the septum without turning into it.

Vessels and Nerves.—The arteries supplying the heart are the left or anterior and right or posterior coronary (page 542).

The veins accompany the arteries, and terminate in the right auricle. They are
the great, the middle, anterior, and posterior, cardiac veins, the right or small and the left or great coronary sinuses, and the vena cordis minima (venae Thebesii) (p. 677).

The lymphatics terminate in the thoracic and right lymphatic duets.

The nerves are derived from the cardiac plexuses, which are formed partly from the cranial nerves and partly from the sympathetic. They are freely distributed both on the surface and in the substance of the heart, the separate filaments being furnished with small ganglia.

Surface Form.—In order to show the extent of the heart in relation to the front of the chest, draw a line from the lower border of the second left costal cartilage, one inch from the sternum, to the upper border of the third right costal cartilage, half an inch from the sternum. This represents the base-line or upper limit of the organ. Take a point an inch and a half below and three-quarters of an inch internal to the left nipple—that is, about three and a half inches to the left of the median line of the body. This represents the apex of the heart. Draw a line from this apex-point, with a slight convexity downward, to the junction of the seventh right costal cartilage to the sternum. This represents the lower limit of the heart. Join the right extremity of the first line—that is, the base-line—with the right extremity of this line—that is, to the seventh right chondro-sternal joint—with a slight curve outward, so that it projects about an inch and a half from the middle line of the sternum. Lastly, join the left extremity of the base-line and the apex-point by a line curved slightly to the left.

The position of the various orifices is as follows: viz. the pulmonary orifice is situated in the upper angle formed by the articularation of the third left costal cartilage with the sternum; the aortic orifice is a little below and internal to this, behind the left border of the sternum, close to the articularation of the third left costal cartilage to this bone. The left auriculo-ventricular opening is behind the sternum, rather to the left of the median line, and opposite the fourth costal cartilages. The right auriculo-ventricular opening is a little lower, opposite the fourth intercostal space and in the middle line of the body.

A portion of the area of the heart thus mapped out is uncovered by lung, and therefore gives a dull note on percussion; the remainder, being overlapped by the lung, gives a more or less resonant note. The former is known as the area of superficial cardiac dulness; the latter as the area of deep cardiac dulness. The area of superficial cardiac dulness is included between a line drawn from the centre of the sternum, between the fourth costal cartilages, to the apex of the heart and a line drawn from the same point down the lower third of the middle line of the sternum. Below, this area merges into the dulness which corresponds to the liver. Dr. Latham lays down the following rule as a sufficient practical guide for the definition of the portion of the heart which is uncovered by lung or pleura: "Make a circle of two inches in diameter round a point midway between the nipple and the end of the sternum," that is, the gladiolus.

Peculiarities in the Vascular System of the Fetus.

The chief peculiarities in the heart of the fetus are the direct communication between the two auricles through the foramen ovale and the large size of the Eustachian valve. There are also several minor peculiarities. Thus, the position of the heart is vertical until the fourth month, when it commences to assume an oblique direction. Its size is also very considerable as compared with the body, the proportion at the second month being 1 to 50; at birth it is as 1 to 120; whilst in the adult the average is about 1 to 160. At an early period of foetal life the auricular portion of the heart is larger than the ventricular, the right auricle being more capacious than the left; but toward birth the ventricular portion becomes the larger. The thickness of both ventricles is at first about equal, but toward birth the left becomes much the thicker of the two.

The foramen ovale is situated at the lower and back part of the septum auriculare, forming a communication between the auricles. It remains as a free oval opening from the time of the formation of the auricular septum (about the eighth week) until the middle period of foetal life. About this period a fold grows up from the posterior wall of the auricle to the left of the foramen ovale, and advances over the opening so as to form a sort of valve, which allows the blood to pass only from the right to the left auricle, and not in the opposite direction.

The Eustachian valve is developed from the anterior border of the inferior vena cava at its entrance into the auricle. It is directed upward on the left side of the opening of this vein, and serves to direct the blood from the inferior vena cava through the foramen ovale into the left auricle.

The peculiarities in the arterial system of the fetus are the communication between the pulmonary artery and the descending aorta by means of the ductus
arteriosus, and the communication between the internal iliac arteries and the placenta by means of the umbilical arteries.

The ductus arteriosus is a short tube, about half an inch in length at birth, and of the diameter of a goosequill. In the early condition it forms the continuation of the pulmonary artery, and opens into the descending aorta just below the origin of the left subclavian artery, and so conducts the chief part of the blood from the right ventricle into this vessel. When the branches of the pulmonary artery have become larger relatively to the ductus arteriosus, the latter is chiefly connected to the left pulmonary artery; and the fibrous cord, which is all that remains of the ductus arteriosus in later life, will be found to be attached to the root of that vessel.

The umbilical or hypogastric arteries arise from the internal iliacs, in addition to the branches given off from those vessels in the adult. Ascending along the sides of the bladder to its fundus, they pass out of the abdomen at the umbilicus, and are continued along the umbilical cord to the placenta, coiling round the umbilical vein. They return to the placenta the blood which has circulated in the system of the foetus.

The peculiarity in the venous system of the foetus is the communication established between the placenta and the liver and portal vein through the umbilical vein, and the inferior vena cava through the ductus venosus.

FETAL CIRCULATION.

The blood destined for the nutrition of the foetus is carried from the placenta to the foetus, along the umbilical cord, by the umbilical vein. The umbilical vein enters the abdomen at the umbilicus, and passes upward along the free margin of the suspensory ligament of the liver to the under surface of that organ, where it gives off two or three branches to the left lobe, one of which is of large size, and others to the lobus quadratus and lobulus Spigelli. At the transverse fissure it divides into two branches: of these, the larger is joined by the portal vein and enters the right lobe; the smaller branch continues onward, under the name of the ductus venosus, and joins the left hepatic vein at the point of junction of that vessel with the inferior vena cava. The blood, therefore, which traverses the umbilical vein reaches the inferior vena cava in three different ways: the greater quantity circulates through the liver with the portal venous blood before entering the vena cava by the hepatic veins; some enters the liver directly, and is also returned to the inferior cava by the hepatic veins; the smaller quantity passes directly into the vena cava by the junction of the ductus venosus with the left hepatic vein.

In the inferior cava the blood carried by the ductus venosus and hepatic veins becomes mixed with that returning from the lower extremities and wall of the abdomen. It enters the right auricle, and, guided by the Eustachian valve, passes through the foramen ovale into the left auricle, where it becomes mixed with a small quantity of blood returned from the lungs by the pulmonary veins. From the left auricle it passes into the left ventricle, and from the left ventricle into the aorta, by means of which it is distributed almost entirely to the head and upper extremities, a small quantity being probably carried into the descending aorta. From the head and upper extremities the blood is returned by the branches of the superior vena cava to the right auricle, where it becomes mixed with a small portion of the blood from the inferior cava. From the right auricle it descends over the Eustachian valve into the right ventricle, and from the right ventricle passes into the pulmonary artery. The lungs of the foetus being solid and almost impervious, only a small quantity of the blood of the pulmonary artery is distributed to them by the right and left pulmonary arteries, and is returned by the pulmonary veins to the left auricle; the greater part passes through the ductus arteriosus into the commencement of the descending aorta, where it becomes mixed with a small quantity of blood transmitted by the left ventricle into the aorta.
Along this vessel it descends to supply the lower extremities and viscera of the abdomen and pelvis, the chief portion being, however, conveyed by the umbilical arteries to the placenta.

From the preceding account of the circulation of the blood in the fetus it will be seen—

1. That the placenta serves the double purpose of a respiratory and nutritive organ, receiving the venous blood from the fetus, and returning it again re-oxygenated and charged with additional nutritive material.

2. That nearly the whole of the blood of the umbilical vein traverses the liver.
before entering the inferior cava; hence the large size of this organ, especially at an early period of foetal life.

3. That the right auricle is the point of meeting of a double current, the blood in the inferior cava being guided by the Eustachian valve into the left auricle, whilst that in the superior cava descends into the right ventricle. At an early period of foetal life it is highly probable that the two streams are quite distinct, for the inferior cava opens almost directly into the left auricle, and the Eustachian valve would exclude the current along the vein from entering the right ventricle. At a later period, as the separation between the two auricles becomes more distinct, it seems probable that some mixture of the two streams must take place.

4. The blood carried from the placenta to the foetus by the umbilical vein, mixed with the blood from the inferior cava, passes almost directly to the arch of the aorta, and is distributed by the branches of that vessel to the head and upper extremities; hence the large size and perfect development of those parts at birth.

5. The blood contained in the descending aorta, chiefly derived from that which has already circulated through the head and upper limbs, together with a small quantity from the left ventricle, is distributed to the lower extremities; hence the small size and imperfect development of these parts at birth.

Changes in the Vascular System at Birth.

At birth, when respiration is established, an increased amount of blood from the pulmonary artery passes through the lungs, which now perform their office as respiratory organs, and at the same time the placental circulation is cut off. The foramen ovale becomes gradually closed by about the tenth day after birth; the valvular fold above mentioned becomes adherent to the margins of the foramen for the greater part of its circumference, but above a slit-like opening is left between the two auricles which sometimes remains persistent.

The ductus arteriosus begins to contract immediately after respiration is established, becomes completely closed from the fourth to the tenth day, and ultimately degenerates into an impervious cord which serves to connect the left pulmonary artery to the descending aorta.

Of the umbilical or hypogastric arteries, the portion continued on to the bladder from the trunk of the corresponding internal iliac remains pervious as the superior vesical artery, and the part between the fundus of the bladder and the umbilicus becomes obliterated between the second and fifth days after birth, and projects into the peritoneal sac so as to form the two fossæ of the peritoneum spoken of in the section on the surgical anatomy of direct inguinal hernia.

The umbilical vein and ductus venosus become completely obliterated between the second and fifth days after birth, and ultimately dwindle to fibrous cords; the former becoming the round ligament of the liver, the latter the fibrous cord, which in the adult may be traced along the fissure of the ductus venosus.

Measurements of the Thorax.

Perimeters.

At the level of the highest point of the axilla ......................................... 89.52 cm.

nipple ........................................ 86.64 cm.

sterno-xiphoid articulation .................. 81.88 cm.

Diameters.

Transverse, between the eighth intercostal spaces ................................... 28 cm.

Antero-posterior, at the level of the ensiform cartilage ............................ 20 cm.

Vertical, anterior wall .................................................................................. 15.5 cm.

posterior wall ....................................................................................... 31.5 cm.

(2.54 cm. = 1 inch.) (Joessel.)
THE ORGANS OF VOICE AND RESPIRATION.

THE LARYNX.

The Larynx is the organ of voice, placed at the upper part of the air-passage. It is situated between the trachea and base of the tongue, at the upper and fore part of the neck, where it forms a considerable projection in the middle line. On either side of it lie the great vessels of the neck; behind, it forms part of the anterior boundary of the pharynx, and is covered by the mucous membrane lining that cavity.

The larynx is broad above, where it presents the form of a triangular box, flattened behind and at the sides, and bounded in front by a prominent vertical ridge. Below, it is narrow and cylindrical. It is composed of cartilages which are connected together by ligaments and moved by numerous muscles; the interior is lined by mucous membrane and supplied with vessels and nerves.

The Cartilages of the Larynx are nine in number, three single and three pairs:

The Thyroid (θυρόστροφος, a shield) is the largest cartilage of the larynx. It consists of two lateral lamellae or ale, united at an acute angle in front, forming a vertical projection in the middle line which is prominent above and called the pomum Adami. This projection is subcutaneous, more distinct in the male than in the female, and occasionally separated from the integument by a bursa mucosa.

Each lamella is quadrilateral in form. Its outer surface presents an oblique ridge which passes downward and forward from a tubercle situated near the root of the superior cornu. This ridge gives attachment to the Sterno-thyroid and Thyro-hyoid muscles, and the portion of cartilage included between it and the posterior border, to part of the Inferior constrictor muscle.

The inner surface of each ala is smooth, slightly concave, and covered by mucous membrane above and behind; but in front, in the receding angle formed by their junction, are attached the epiglottis, the true and false vocal cords, the Thyro-arytenoid and Thyro-epiglottidean muscles.

The upper border of the thyroid cartilage is sinuously curved, being concave at its posterior part, just in front of the superior cornu, and then rising into a convex outline, which dips, in front, to form the sides of a notch or incisura in the middle line immediately above the pomum Adami. This border gives attachment throughout its whole extent to the thyro-hyoid membrane.
From above the lower border posteriorly, there passes to the cricoid cartilage, in and on each side of the median line, the crico-thyroid membrane, on each side of which is the Crico-thyroid muscle.

The posterior borders terminate above in the superior cornua, and below in the inferior cornua. The two superior cornua, long and narrow, directed upward, backward, and inward, terminate each in a conical extremity which gives attachment to the lateral thyro-hyoid ligament. The two inferior cornua are short and thick; they pass downward, with a slight inclination forward and inward, and present each on its inner surface a small oval articular facet for articulation with the side of the cricoid cartilage. On the posterior border are inserted the Stylo-pharyngeus and Palato-pharyngeus muscles.

The Cricoid Cartilage is so called from its resemblance to a signet-ring (ξυξών; a ring). It is smaller, but thicker and stronger than the thyroid cartilage, and forms the lower part of the cavity of the larynx.

Its anterior half (annulus) is narrow, convex, affording attachment at the sides to the Cricothyroid muscles, and behind to part of the Inferior constrictor.

Its posterior half (lamina) is very broad both from side to side and from above downward; it presents posteriorly in the middle line a vertical ridge (linea eminens) for the attachment of the longitudinal fibres of the oesophagus, and on either side a broad depression (fovea) for the Crico-arytenoideus posterior muscle.

At the point of junction of the two halves of the cartilage on either side is a small round elevated facet for articulation with the inferior cornu of the thyroid cartilage.

The lower border of the cricoid cartilage is horizontal and connected to the upper ring of the trachea by fibrous membrane.

Its upper border is directed obliquely upward and backward, owing to the height of the lamina. The upper border of the lamina is surmounted on each end by a smooth, oval facet for articulation with the arytenoid cartilage. Between these articular surfaces is a slight notch. To the rest of the upper border of the entire cartilage, all the way around from one arytenoid facet to the other, is attached the Crico-thyro-arytenoid ligament, and externally to this, at the sides, the lateral Crico-arytenoid muscle.

The inner surface of the cricoid cartilage is smooth and lined by mucous membrane.
The **Arytenoid Cartilages**, so called from ἀρύθενδος, a ladle, are two in number, and each is situated at the end of the upper border of the lamina of the cricoid cartilage. Each cartilage is pyramidal in form, and presents for examination three surfaces, a base, and an apex.

The **posterior surface** is triangular, smooth, concave, and gives attachment to the Arytenoid muscle.

The **antero-external surface** is convex and rough. It gives attachment to the Thyro-arytenoid muscle; and to the false vocal cord immediately above a depression, the fossa triangularis, situated at about its centre.

The **internal surface** is narrow, smooth, and flattened, covered by mucous membrane, and lies almost in apposition with the cartilage of the opposite side.

The **base** of each cartilage is broad, and presents a concave (antero-posteriorly) smooth surface for articulation with the cricoid cartilage. Projecting from the base are two processes, one postero-externally and the other anteriorly. Between the two is the base of the antero-external surface. The former, known as the muscular process, is short, rounded, and prominent, and receives the insertion of the Posterior and Lateral crico-arytenoid muscles. The latter also prominent, but more pointed and flattened, gives attachment to the true vocal cord. This is the vocal process.

The **apex** of each cartilage is pointed, curved backward and inward, and surmounted by a small, cone-shaped, cartilaginous nodule, the corniculum laryngis.

The **cornicula laryngis** (cartilages of Santorini) are two small, conical nodules, consisting of yellow fibro-cartilage, which are attached to the summit of the arytenoid cartilages and serve to prolong them backward and inward. To them are attached the aryteno-epiglottic folds. They are sometimes united to the arytenoid cartilages.

The **cuneiform cartilages** (cartilages of Wrisberg) are two small, elongated, cartilaginous bodies, placed one on each side in the fold of mucous membrane, which extends from the apex of the arytenoid cartilage to the side of the epiglottis (aryteno-epiglottic fold); they give rise to small whitish elevations on the free edge of the mucous fold, just in front of the cartilages of Santorini.

The **epiglottis** is a thin lamella of fibro-cartilage, of a yellowish color, shaped like a leaf, and placed behind the tongue, in front of the superior opening of the larynx. During respiration its direction is vertically upward, its free extremity curves forward toward the base of the tongue; but when the larynx is drawn up beneath the base of the tongue during deglutition, it is carried downward and backward so as to close, more or less completely, the opening of the larynx. Its free extremity is broad and rounded; its attached end is long and narrow, and connected to the receding angle between the two sides of the thyroid cartilage, just below the median notch, by a ligamentous band, the thyro-epiglottic ligament. It is also connected to the posterior surface of the body of the hyoid bone by an elastic ligamentous band, the hypo-epiglottic ligament.

Its **anterior or lingual surface** is curved forward toward the tongue, and covered at its upper part by mucous membrane, which is reflected on to the sides and base of the organ, forming a median and two lateral folds, the glossop-epiglottic folds.

Its **posterior or laryngeal surface** is smooth, concave from side to side, concavo-convex from above downward, and covered by mucous membrane; when this is removed the surface of the cartilage is seen to be studded with a number of little pits for the lodgment of mucous glands. To its sides the aryteno-epiglottic folds are attached. It is somewhat prominent just below its centre (tubercle or cushion of the epiglottis).

**Structure.**—The cornicula laryngis, cuneiform cartilages, and epiglottis are composed of yellow fibro-cartilage which shows little tendency to calcification, but the other cartilages are hyaline, becoming more or less calcified in old age.

**Ligaments.**—The ligaments of the larynx connect the thyroid cartilage and epiglottis with the hyoid bone, the cricoid cartilage with the trachea, and the several cartilages of the larynx to each other.
The Thyro-hyoid Ligaments.—These constitute the thyo-hyoid membrane, and the middle and two lateral thyo-hyoid ligaments.

The middle thyo-hyoid ligament consists of tough, yellowish fibro-elastic tissue. Its lower border is attached in the thyroid notch; its upper to the upper border of the posterior surface of the body of the hyoid bone, thus passing behind its posterior surface, and being separated from it by a synovial bursa (sub-hyoid bursa). When the thyo-hyoid membrane is removed, the lateral borders of this ligament are seen to be free.

The two lateral thyo-hyoid ligaments are rounded elastic cords, which pass between the superior cornua of the thyroid cartilage and the extremities of the greater cornua of the hyoid bone. A small cartilaginous nodule (cartilago triticea), sometimes bony, is frequently found in each.

The thyo-hyoid membrane fills in the interval between each lateral thyo-hyoid ligament and the free edge of the middle one. In this situation it is made up of two layers, cellular tissue externally and mucous membrane internally and, just in front of the lateral ligament, its cellular layer is pierced by the superior laryngeal vessels and nerve. The cellular layer is attached all the way around, above to the cornua and body of the hyoid bone, and below to the entire upper border, incisura as well, of the thyroid cartilage. It thus passes in front of the middle thyo-hyoid ligament, and here forms the anterior wall of the sub-hyoid bursa. At the free edge of the middle ligament the mucous membrane passes behind the epiglottis; at the lateral ligament it is reflected on to the posterior wall of the pharynx.

The hyo-epiglottic ligament is a fibrous band, which extends from the anterior surface of the epiglottis to the upper border of the body of the hyoid bone. The thyo-epiglottic ligament connects the apex of the epiglottis with the receding angle of the thyroid cartilage just beneath the median notch.

The Crico-thyro-arytenoid Ligament.—This is a strong fibrous lamina, bent on itself anteriorly. Its attachments are as follows: (1) Posteriorly, it is attached to the vocal process of one arytenoid cartilage, whence it extends as a free edge in a practically straight line, forward and a little inward, to the posterior aspect of the angle between the alae of the thyroid cartilage. Here it bends on itself at an acute angle, is attached to the thyroid, and passes backward and a little outward, as a second free edge, to be attached to the vocal process of the other arytenoid cartilage. (2) From these two free edges, as an upper limit, the lamina passes downward, with an outward slope, to the curved sloping upper border of the cricoid cartilage which lies anterior to the lamina of the same, and becomes attached to it in its entire extent. The ligament, as a whole, is thus seen to be V-shaped above, apex forward, but of a curved outline below. Furthermore, its vertical diameter varies, being smallest behind and greatest in front at the middle line, this variation being due to the upper border of the cricoid, which slopes upward posteriorly until it almost reaches the vocal process of the arytenoid.

In the middle line the angle which is formed in front by the bending on itself of this ligament is acute above, but obtuse or "rounded" below. The upper part of this "angle" lies behind and attached to the angle of the thyroid cartilage, its upper limit (i. e. the angle of the free edges) being at some distance (almost halfway up) from the lower edge of the cartilage. The lower or "rounded" part is the direct continuation downward of the upper, and passes to the middle of the upper border of the cricoid. This last is known as the crico-thyroid membrane, is subcutaneous, and is crossed by a small anastomotic arterial arch from the two crico-thyroid arteries.

Laterally, there is a considerable interval between the outer surface of this ligament and the inner surface of the corresponding half of the thyroid cartilage, which is filled in by the Thyro-arytenoid and Lateral crico-arytenoid muscles.

The upper free edges of this ligament are thicker than the remainder, and are known as the inferior thyo-arytenoid ligaments. When covered with mucous membrane they constitute the true vocal cords. The inner surfaces of the crico-thyro-
arytenoid ligament are covered by mucous membrane prolonged from that of the true cords, and are the lateral boundaries of this portion of the cavity of the larynx.

The Crico-thyroid Ligaments.—These are capsular ligaments which enlose on each side the articulation of the inferior cornu of the thyroid with the cricoid cartilage. The articulation is lined by synovial membrane, and strengthened by accessory (kerato-cricoid) ligaments which pass from the tip of the cornu in various directions to the cricoid.

The crico-arytenoid ligaments are two capsular and two posterior. The capsular are thin and loose capsules attached to the margins of the articular surfaces; they are lined internally by synovial membrane. The posterior extend from the cricoid to the inner and back part of the base of the arytenoid cartilage.

The crico-tracheal ligament connects the cricoid cartilage with the first ring of the trachea. It resembles the fibrous membrane, which connects the rings of the trachea to each other.

Interior of the Larynx.—The superior aperture of the larynx (Fig. 701) is a cordiform opening, wide in front, narrow behind, and sloping obliquely downward and backward. It is bounded in front by the epiglottis, behind by the inter-arytenoid fold of mucous membrane passing between the arytenoid cartilages, and laterally, by a fold of mucous membrane enclosing areolar tissue and muscular fibres, stretched between the sides of the epiglottis and the apex of the arytenoid cartilages: these are the aryteno-epiglottic folds, on the margins of which the cuneiform cartilages and cornicula form more or less distinct whitish prominences.

The cavity of the larynx extends from the superior aperture to the lower border of the cricoid cartilage. It is divided into two parts by the projection inward of the true vocal cords; between the two cords is a long and narrow triangular fissure or chink, the glottis, of which the boundary is the rima glottidis. The portion of the cavity of the larynx above the true vocal cords is broad, and contains the false vocal cords, between each of which and the corresponding true vocal cord is the corresponding ventricle of the larynx. The portion below the true vocal cords is at first elliptical, and lower down circular, in form.

The glottis is the narrow fissure or chink between the inferior or true vocal cords in front (inter-ligamentous portion), and the vocal processes of the arytenoid cartilages behind (intercartilaginous portion). It is the narrowest part of the cavity of the larynx. Its length in the male measures rather less than an inch, its breadth when dilated varying at its widest part from a third to half an inch. The form of the glottis varies. In its half-closed condition it is a narrow fissure, a little enlarged and rounded behind. In quiet breathing it is somewhat triangular, the base of the triangle directed backward, and corresponding to the space between the arytenoid cartilages. When widely open it is lozenge-shaped. In forcible expiration it is smaller than during inspiration. When sound is produced it is more narrowed, the edges of the vocal cords being approximated and made parallel, the approximation and tension corresponding to the height of the note produced.1

1 On the shape of the rima glottidis in the various conditions of breathing and speaking, see Czermak, On the Laryngoscope, translated for the New Sydenham Society.
The superior or false vocal cords, so called because they are not directly concerned in the production of the voice, are two folds of mucous membrane, each enclosing a delicate rounded band, the superior thyro-arytenoid ligament. This ligament consists of areolar tissue, attached in front to the angle of the thyroid cartilage below the epiglottis, and behind to the antero-external surface of the arytenoid cartilage, just above the fossa triangularis. This ligament, enclosed in mucous membrane, forms a free margin, which constitutes the upper boundary of the corresponding ventricle of the larynx.

The inferior or true vocal cords, so called from their being concerned in the production of sound, are two strong fibrous bands (inferior thyro-arytenoid ligaments), covered on their surface by a thin layer of mucous membrane. These ligaments have already been described. Each forms the lower boundary of the corresponding ventricle of the larynx. Externally, the Thyro-arytenoideus (inner portion) muscle lies parallel with it.

The ventricle of the larynx is an oblong fossa situated between the superior and inferior vocal cords on each side, and extending nearly their entire length. This fossa is bounded above by the free crescentic edge of the superior vocal cord, below by the straight margin of the true vocal cord, externally by the mucous membrane covering the inner surface of the corresponding Thyro-arytenoideus muscle (outer portion). The anterior part of the ventricle leads up by a narrow opening into a ceecal pouch of mucous membrane of variable size called the laryngeal pouch.

The sacculus laryngis, or laryngeal pouch, is a membranous sac placed between the superior vocal cord and the inner surface of the thyroid cartilage, occasionally extending as far as its upper border; it is conical in form, and curved slightly backward. On the surface of its mucous membrane are the openings of sixty or seventy small follicular glands which are lodged in the submucous areolar tissue. This sac is enclosed in a fibrous capsule continuous below with the superior thyro-arytenoid ligament; its laryngeal surface is covered by muscular fibres derived from those found in the aryteno-epiglottic fold (Aryteno-epiglottideus inferior muscle, Compressor sacculi laryngis, Hilton), whilst its exterior is covered by the Thyro-arytenoideus and Thyro-epiglottideus muscles.

Muscles.—The muscles of the larynx are eight in number, and are as follows:

The Cricoid-thyroid is triangular in form, and situated at the fore part and side of the cricoid cartilage. It arises from the front and lateral part of the cricoid cartilage; its fibres diverge, passing obliquely upward and outward to be inserted into the lower border of the thyroid cartilage and into the anterior border of the lower cornua.

The inner borders of these two muscles are separated in the middle line by a triangular interval occupied by the crico-thyroid membrane.

The Crico-arytenoideus posticus arises from the broad depression occupying each lateral half of the posterior surface of the lamina of the cricoid cartilage; its fibres pass upward and outward, converging to be inserted into the muscular pro-
cess of the base of the arytenoid cartilage. The upper fibres are nearly horizontal, the middle oblique, and the lower almost vertical.  

The Crico-arytenoideus lateralis is smaller than the preceding, and of an oblong form. It arises from the upper border of the side of the cricoid cartilage, and, passing obliquely upward and backward, is inserted into the muscular process of the base of the arytenoid cartilage in front of the preceding muscle.

The Arytenoideus is a single muscle filling up the posterior concave surface of the arytenoid cartilages. It arises from the posterior surface and outer border of one arytenoid cartilage, and is inserted into the corresponding parts of the opposite cartilage. It consists of three planes of fibres, two oblique and one transverse. The oblique fibres, the most superficial, form two fasciculi,

which pass from the base of one cartilage to the apex of the opposite one. The transverse fibres, the deepest and most numerous, pass transversely across between the two cartilages; hence the Arytenoideus was formerly considered as several muscles, under the name of transversi and obliqui. A few of the oblique fibres are usually continued round the outer margin of the cartilage, and blend with the Thyro-arytenoideus or the Aryteno-epiglottideus superior muscle.

The Thyro-arytenoideus is a broad, flat muscle, which lies parallel with the outer side of the true vocal cord. It arises in front from the lower half of the receding angle of the thyroid cartilage and from the crico-thyroid membrane. Its fibres pass backward and outward, to be inserted into the arytenoid cartilage. This muscle consists of two fasciculi. The inner portion, the thicker, is inserted into the vocal process of the base of the arytenoid cartilage and into the adjacent por-

1 Dr. Merkel of Leipsic has described a muscular slip which occasionally extends between the outer border of the posterior surface of the cricoid cartilage and the posterior margin of the inferior cornu of the thyroid; this he calls the "Musculus kerato-cricoides." It is not found in every larynx, and when present exists usually only on one side, but is occasionally found on both sides. Sir William Turner (Edinburgh Medical Journal, Feb., 1860) states that it is found in about one case in five. Its action is to fix the lower horn of the thyroid cartilage backward and downward, opposing in some measure the part of the Crico-thyroid muscle which is connected to the anterior margin of the horn.

2 The arytenoideus rectus (Laschka) is a small slip passing between the posterior surface of the arytenoid cartilage below to the cartilage of Santorini (corniculum) above. Anatomy, Hyrtl, p. 718.
tion of its antero-external surface; it lies parallel with the true vocal cord, to which it is adherent. The outer or superior fasciculus, the thinner, is inserted into the muscular process and outer border of the arytenoid cartilage above the preceding fibres; it lies on the outer side of the sacculus laryngis.\(^1\)

The *Thyro-epiglottideus* is a delicate fasciculus which arises from the angle of the thyroid cartilage, close to the origin of the Thyro-arytenoid, and spreads out upon the outer surface of the sacculus laryngis; some of its fibres are lost in the aryteno-epiglottic fold, whilst others pass to the margin of the epiglottis (*Depressor epiglottis*).

The *Aryteno-epiglottideus superior* consists of a few delicate fasciculi, which arise from the apex of the arytenoid cartilage and become lost in the aryteno-epiglottic fold.

The *Aryteno-epiglottideus inferior* (*Compressor sacculi laryngis*, Hilton), arises from the arytenoid cartilage just below the preceding; and passes forward and upward, it spreads out upon the inner surface of the laryngeal pouch.\(^2\)

**Actions.**—In considering the action of the muscles of the larynx, they may be conveniently divided into two groups, viz.: 1. Those which open and close the glottis. 2. Those which regulate the degree of tension of the vocal cords.

1. The muscles which open the glottis are the Crico-arytenoidi postici; and those which close it are the Arytenoideus and the Crico-arytenoidei laterales.

2. The muscles which regulate the tension of the vocal cords are the Crico-arytenoidei, which tense and elongate them; and the Thyro-arytenoidei, which relax and shorten them. The Thyro-epiglottideus is a depressor of the epiglottis, and the Aryteno-epiglottidei constrict the superior aperture of the larynx, compress the sacculi laryngis, and empty them of their contents.

The *Crico-arytenoidei postici* separate the chordæ vocales, and consequently open the glottis, by rotating the arytenoid cartilages outward around a vertical axis passing through the crico-arytenoid joints, so that their anterior angles and the ligaments attached to them become widely separated, the vocal cords at the same time being made tense.

The *Crico-arytenoidei laterales* close the glottis by rotating the arytenoid cartilages inward so as to approximate their anterior angles.

The *Arytenoideus muscles* approximate the arytenoid cartilages, and thus close the opening of the glottis, especially at its back part. The *Crico-thyroid muscles* produce tension and elongation of the vocal cords. This is effected as follows: the thyroid cartilage is fixed by the Thyro-hyoid muscles; then the Crico-thyroid muscles, when they act, draw upward the front of the cricoïd cartilage, and so depress the posterior portion, which carries with it the arytenoid cartilages, and thus elongate the vocal cords.

The *Thyro-arytenoidei muscles*, consisting of two parts having different attachments and different directions, are rather complicated as regards their action. Their main use is to draw the arytenoid cartilages forward toward the thyroid, and thus shorten and relax the vocal cords. But, owing to the connection of the inner portion with the vocal cord, this part, if acting separately, is supposed to modify its elasticity and tension, and the outer portion, being inserted into the outer part of the anterior surface of the arytenoid cartilage, may rotate it inward, and thus narrow the rima glottidis by bringing the two cords together.

The *Thyro-epiglottidei* depress the epiglottis and assist in compressing the sacculi laryngis. The Aryteno-epiglottideus superior constricts the superior aperture of the larynx, when it is drawn upward, during deglutition, and the opening closed by the epiglottis. The Aryteno-epiglottideus inferior, together with some fibres of the Thyro-arytenoidei, compress the saccula laryngis.

The **Mucous Membrane of the Larynx** is continuous above with that lining the mouth and pharynx, and is prolonged through the trachea and bronchi into the lungs. It lines the posterior and upper part of the anterior surface of the epiglottis, to which it is closely adherent, and forms the aryteno-epiglottic folds which

---

1 Henle describes these two portions as separate muscles, under the names of External and Internal thyro-arytenoid.

2 **Musculus triticeo-glossis**, Bochdalek, jun. *(Prager Vierteljahrschrift, 2d part, 1866)*, describes a muscle hitherto entirely overlooked, except a brief statement in Henle's *Anatomy*, which arises from the nodule of cartilage (*corpus triticeum*) in the posterior thyro-hyoid ligament, and passes forward and upward to enter the tongue along with the Hyo-glossus muscle. He met with this muscle eight times in twenty-two subjects. It occurred in both sexes, sometimes on both sides, at others on one only.
encircle the superior aperture of the larynx. It lines the whole of the cavity of the larynx; forms, by its reduplication, the chief part of the superior or false vocal cord; and, from the ventricle, is continued into the sacculus laryngis. It is then reflected over the true vocal cords, where it is thin and very intimately adherent; covers the inner surface of the crico-thyroid membrane and cricoid cartilage; and is ultimately continuous with the lining membrane of the trachea. It is covered with columnar ciliated epithelium below the superior vocal cord, but above this point the cilia are found only in front, as high as the middle of the epiglottis. In the rest of its extent the epithelium is of the squamous variety; as is also that covering the true vocal cords.

Glands.—The mucous membrane of the larynx is furnished with numerous muciparous glands, the orifices of which are found in nearly every part; they are very numerous upon the epiglottis, being lodged in little pits in its substance; they are also found in large numbers along the posterior margin of the aryteno-epiglottidean fold, in front of the arytenoid cartilages, where they are termed the arytenoid glands. They exist also in large numbers upon the inner surface of the sacculus laryngis. None are found on the vocal cords.

Vessels and Nerves.—The arteries of the larynx are the laryngeal branches derived from the superior and inferior thyroid. The veins accompany the arteries: those accompanying the superior laryngeal artery join the superior thyroid vein which opens into the internal jugular vein; while those accompanying the inferior laryngeal artery join the inferior thyroid vein which opens into the innominate vein. The lymphatics terminate in the deep cervical glands. The nerves are the superior laryngeal and the inferior or recurrent laryngeal branches of the pneumogastric nerves, joined by filaments from the sympathetic. The superior laryngeal nerves supply the mucous membrane of the larynx and the Crico-thyroid muscles. The inferior laryngeal nerves supply the remaining muscles. The Arytenoid muscle is supplied by both nerves.

THE TRACHEA (Fig. 705).

The Trachea, or Windpipe, is a cartilaginous and membranous cylindrical tube, flattened posteriorly, which extends from the lower part of the larynx, on a level with the sixth cervical vertebra, to opposite the fourth, or sometimes the fifth, dorsal, where it divides into the two bronchi, one for each lung. The trachea measures about four inches and a half in length (10–11 cm.); its diameter, from side to side, is from three-quarters of an inch to an inch (2–2½ cm.), being always greater in the male than in the female.

Relations.—The anterior surface of the trachea is convex, and covered in the neck, from above downward, by the isthmus of the thyroid gland, the inferior thyroid veins, the arteria thyroidea ima (when that vessel exists), the Sterno-hyoid and Sterno-thyroid muscles, the cervical fascia, and more superficially, by the anastomosing branches between the anterior jugular veins: in the thorax it is covered from before backward by the first piece of the sternum, the remains of the thymus gland, the left innominate vein, the arch of the aorta, the innominate and left common carotid arteries, and the deep cardiac plexus. Posteriorly, it is in relation with the oesophagus; laterally, in the neck, it is in relation with the common carotid arteries, the lateral lobes of the thyroid gland, the inferior thyroid arteries, and recurrent laryngeal nerves; and in the thorax it lies in the space between the pleure (superior mediastinum); having the pneumogastric nerve on each side of it.

The Right Bronchus, wider, shorter, and more horizontal in direction than the left, is about an inch in length, and enters the right lung opposite the fifth dorsal vertebra. The vena azygos major arches over it from behind, and the right pulmonary artery lies below and then in front of it. About three-quarters of an inch from its origin it gives off a branch to the upper lobe of the right lung. This branch is known as eparterial because it is given off above the right pulmonary artery, below which the main bronchus now passes and is known as hyparterial;
the trachea subdivides into two branches for the middle and lower lobes of the right lung.

The Left Bronchus is smaller, longer, and more oblique than the right, being nearly two inches in length. It enters the root of the left lung opposite the sixth dorsal vertebra, about an inch lower than the right bronchus. It passes beneath the arch of the aorta, crosses, in front of the oesophagus, the thoracic duct and

the descending aorta, and has the left pulmonary artery lying at first above and then in front of it. It is entirely hyparterial, having no eparterial branch, and divides into two branches for the upper and lower lobes of the left lung. If a transverse section is made across the trachea a short distance above its point of bifurcation, it is seen, in many cases, on looking down the tube that the right bronchus appears to continue the direction of the trachea more directly than does the left.

Subdivisions of the Bronchi.—According to Aeby, whose observations are based on casts of the trachea and bronchi made with Roser's fusible alloy, the following is the arrangement of the bronchi and larger bronchial tubes (Fig. 706): The right bronchus, after giving off the eparterial branch, becomes hyparterial, which the left bronchus is from the beginning. Each bronchus then passes downward and back-

![Fig. 705.—Front view of cartilages of larynx; the trachea and bronchi.](image-url)
ward, constantly diminishing in calibre until it ends, as such, in the lower and posterior part of the inferior lobe of the corresponding lung. In its course each bronchus gives off four ventral and four dorsal branches, the right bronchus also giving off an additional or accessory bronchus, the so-called "heart-bronchus" which passes mesially and dorsally into the inferior lobe. Its name comes from the fact that it is the homologue of a bronchus which, in certain animals, runs to the infracardiac lobe. Of the right bronchus, the first ventral branch goes to the middle lobe; the other ventral and all the dorsal passing to the inferior lobe. Of the left bronchus, the first ventral branch passes to the superior lobe, all the others, ventral and dorsal, going to the inferior lobe. All these branches, on both sides, are hyparterial as well as the "heart-bronchus." The characteristic general course of each bronchus is outlined in the Diagram.

Structure.—The trachea is composed of imperfect cartilaginous rings, fibrous membrane, muscular fibres, mucous membrane, and glands.

The cartilages vary from sixteen to twenty in number; each forms an imperfect ring which surrounds about two-thirds of the cylinder of the trachea, which is completed behind by fibrous membrane. The cartilages are placed horizontally above each other, separated by narrow membranous intervals. They measure about two lines in depth and half a line in thickness. Their outer surfaces are flattened, but internally they are convex from being thicker in the middle than at the margins. Two or more of the cartilages often unite partially or completely, and are sometimes bifurcated at their extremities. They are highly elastic, but sometimes become calcified in advanced life. In the right bronchus the cartilages vary in number from six to eight; in the left, from nine to twelve. They are shorter and narrower than those of the trachea.
The first cartilage is broader than the rest, and sometimes divided at one end; it is connected by fibrous membrane with the lower border of the cricoid cartilage, with which or with the succeeding cartilage it is sometimes blended. The last cartilage is thick and broad in the middle, in consequence of its lower border being prolonged into a triangular hook-shaped process which curves downward and backward between the two bronchi. It terminates on each side in an imperfect ring which encloses the commencement of the bronchi. The cartilage above the last is somewhat broader than the rest at its centre.

The Fibrous Membrane.—The cartilages are enclosed in an elastic fibrous membrane which forms a double layer, one layer, the thicker of the two, passing over the outer surface of the ring, the other over the inner surface; at the upper and lower margins of the cartilages these two layers blend together to form a single membrane, which connects the rings one with another. They are thus, as it were, imbedded in the membrane. In the space behind, between the extremities of the rings, the membrane forms a single distinct layer.

The muscular fibres are of the unstriped variety and are disposed in two layers, transverse and longitudinal.

The transverse fibres (Trachealis muscle, Todd and Bowman), the most internal, form a thin layer which extends transversely between the ends of the cartilages in the intervals between them at the posterior part of the trachea. Outside of or posterior to these are a few bundles of longitudinal fibres.

The Mucous Membrane is continuous above with that of the larynx, and below with that of the bronchi. Microscopically, it presents a well-marked basement membrane supporting a layer of columnar ciliated epithelium, between the deeper ends of which are smaller round or elongated cells. It contains a large amount of lymphoid tissue and some tracheal glands. Next to the submucous tissue, the mucous membrane contains elastic fibres, most abundant posteriorly, where they are collected into distinct longitudinal bundles. They are especially numerous about the bifurcation of the trachea.

The Tracheal Glands (racemose) are found in great abundance at the posterior part of the trachea. They are small, placed upon the outer surface of the fibrous layer; each is furnished with an excretory duct, which pierces the fibrous and muscular layers and opens on the surface of the mucous membrane. Some glands of smaller size are also found at the sides of the trachea, between the layers of fibrous tissue connecting the rings, and others immediately beneath the mucous coat. The secretion from these glands serves to lubricate the inner surface of the trachea.

Vessels and Nerves.—The trachea is supplied with blood by the inferior thyroid arteries. The veins terminate in the thyroid venous plexus. The nerves are derived from the pneumogastric and its recurrent branches and from the sympathetic.

Surface Form.—In the middle line of the neck some of the cartilages of the larynx can be readily distinguished. In the receding angle below the chin the hyoid bone can easily be made out (see page 283), and a finger's breadth below it is the pomum Adami, the prominence between the upper borders of the two arches of the thyroid cartilage. About an inch below this, in the middle line, is a depression corresponding to the crico-thyroid space, in which the operation of laryngotomy is performed. This depression is bounded below by a prominent arch, the anterior ring of the cricoid cartilage, below which the trachea can be felt, though it is only in the emaciated adult that the separate rings can be distinguished. The lower part of the trachea is not easily made out, for as it descends it is farther removed from the surface. The level of the vocal cords corresponds to the middle of the anterior margin of the thyroid cartilage.

With the laryngoscope the following structures can be seen: The base of the tongue and the upper surface of the epiglottis, with the glosso-epiglottic folds, the superior aperture of the larynx, bounded on either side by the aryteno-epiglottic folds, in which may be seen two rounded eminences corresponding to the cornicula and cuneiform cartilages. Beneath these, the true and false vocal cords, with the ventricle between them. Still deeper, the cricoid cartilage and some of the anterior parts of the rings of the trachea, and sometimes, in deep inspiration, the bifurcation of the trachea.

Surgical Anatomy.—Foreign bodies often find their way into the air-passages. These may be large substances, as a piece of meat, which becomes lodged in the upper aperture of the larynx or in the rima glottidis, and cause speedy suffocation unless rapidly got rid of or unless
THE ORGANS OF VOICE AND RESPIRATION.

an opening is made into the air-passages below. Smaller bodies, such as cherry- or plum-stones, small pieces of bone, buttons, etc., may find their way into the trachea or bronchus, or may become lodged in the ventricle of the larynx. The dangers then depend not so much upon the mechanical obstruction as upon the spasms of the glottis which they excite. When lodged in the ventricle of the larynx they may produce very few symptoms beyond sudden loss of voice or alteration in the voice sounds immediately following the inhalation of the foreign body. When, however, they are situated in the trachea, they are constantly striking against the vocal cords during expiratory efforts, and produce attacks of dyspnea from spasms of the glottis. When lodged in the bronchus they usually become fixed there, and, occluding the lumen of the tube, cause a loss of the respiratory murmur on the affected side, which is usually the right.

Beneath the mucous membrane of the upper part of the air-passages there is a considerable amount of submucous tissue which is liable to become much swollen from effusion in inflammatory affections, constituting the disease known as "œdema of the glottis." This effusion does not extend below the level of the vocal cords, on account of the mucous membrane being closely adherent to these structures. So that in cases of this disease the operation of laryngotomy is sufficient.

Chronic laryngitis, which occurs in those who speak much in public, is known as "clergyman's sore throat." It is due to the large amount of cold air drawn into the air-passages during prolonged speaking.

Ulcration of the larynx may occur from syphilis, either superficial or from the softening of a gumma, from tubercular disease (laryngeal phthisis), or from malignant disease (epitheliam). The air-passages may be opened in two different situations: through the crico-thyroid membrane (laryngotomy), or in some part of the trachea (tracheotomy); and to these some surgeons have added a third method, by opening the crico-thyroid membrane and dividing the cricoid cartilage with the upper ring of the trachea (laryngo-tracheotomy).

Laryngotomy is the most simple, and should always be preferred when particular circumstances do not render the operation of tracheotomy absolutely necessary. The crico-thyroid membrane is very superficial, being covered only in the middle line by the skin, superficial fascia and the deep fascia. On each side of the middle line it is also covered by the Sterno-hyoid and Sterno-thyroid muscles, which diverge slightly from each other at their upper parts, leaving a slight interval between them. On these muscles rests the anterior jugular vein. The only vessel of any importance in connection with this operation is the crico-thyroid artery, which crosses the crico-thyroid membrane, and which may be wounded, but rarely gives rise to any trouble. The operation is performed thus: The crico-thyroid depression having been felt for and found, a vertical incision is then made through the skin in the middle line over this spot, and carried down through the fascia until the crico-thyroid membrane is exposed. A cross cut is then made through the membrane, close to the upper border of the cricoid cartilage, so as to avoid, if possible, the crico-thyroid artery, and a tracheotomy-tube introduced.

Tracheotomy may be performed either above or below the isthmus of the thyroid body, or this structure may be divided and the trachea opened beneath it.

The isthmus of the thyroid gland usually crosses the second and third rings of the trachea; along its upper border is frequently to be found a large transverse communicating branch between the superior thyroid veins; and the isthmus itself is covered by a venous plexus formed between the thyroid veins of the opposite sides. Theoretically, therefore, it is advisable to avoid dividing this structure in opening the trachea.

Above the isthmus the trachea is comparatively superficial, being covered by the skin, superficial fascia, deep fascia, Sterno-hyoid and Sterno-thyroid muscles, and a second layer of the deep fascia, which, attached above to the lower border of the hyoid bone, descends beneath the muscles to the thyroid body, where it divides into two layers and encloses the isthmus.

Below the isthmus the trachea lies much more deeply, and is covered by the Sterno-hyoid and the Sterno-thyroid muscles and a quantity of loose areolar tissue in which is a plexus of veins, some of them of large size; they converge to two trunks, the inferior thyroid veins, which descend on either side of the median line on the front of the trachea and open into the innominate veins. In the infant the thyimus gland ascends a variable distance along the front of the trachea, and opposite the episternal notch the windpipe is crossed by the left innominate vein. Occasionally also, in young subjects, the innominate artery crosses the tube obliquely above the level of the sternum. The thyroidea ima artery, when that vessel exists, passes from below upward along the front of the trachea.

From these observations it must be evident that the trachea can be more readily opened above than below the isthmus of the thyroid body.

Tracheotomy above the isthmus is performed thus: An incision is made from an inch and a half to two inches in length exactly in the median line of the neck from the top of the cricoid cartilage. After the superficial structures have been divided the interval between the Sterno-hyoid muscles must be found, the raphe divided, and the muscles drawn apart. The lower border of the cricoid cartilage must now be felt for, and the upper part of the trachea exposed from this point downward in the middle line. Bose has recommended that the layer of fascia in front of the trachea should be divided transversely at the level of the lower border of the cricoid cartilage, and, having been seized with a pair of forceps, pressed downward with the handle of the scalpel. By this means the isthmus of the thyroid gland is depressed, and is saved from all danger of being wounded, and the trachea cleanly exposed. The trachea is now transfixied with a sharp hook and drawn forward in order to steady it, and is then opened by
THE PLEURÆ.

Each lung is invested, upon its external surface, by an exceedingly delicate serous membrane, the pleura, which encloses the organ as far as its root, and is then reflected upon the inner surface of the thorax. The portion of the serous membrane investing the surface of the lung is called the pleura pulmonalis (visceral layer of pleura), while that which lines the inner surface of the chest is called the pleura costalis (parietal layer of pleura). The space between these two layers is called the cavity of the pleura, but it must be borne in mind that in the healthy condition the two layers are in contact, and there is no real cavity until the lung becomes collapsed and a separation of it from the wall of the chest takes place. Each pleura is therefore a shut sac, one occupying the right, the other the left half of the thorax, and they are perfectly separate, not communicating with each other. The two pleurae do not meet in the middle line of the chest, excepting anteriorly opposite the upper part of the second piece of the sternum—a space being left between them, which contains all the viscera of the thorax excepting the lungs: this is the mediastinum.

Reflections of the Pleura (Fig. 707).—Commencing at the sternum, the pleura passes outward, covers the costal cartilages, the inner surface of the ribs and

Intercostal muscles, and at the back part of the thorax passes over the thoracic ganglia and their branches, and is reflected upon the sides of the bodies of the
vertebræ, where it is separated by a narrow interval, the posterior mediastinum, from the opposite pleura. From the vertebral column the pleura passes to the side of the pericardium, which it covers to a slight extent; it then covers the back part of the root of the lung, from the lower border of which a triangular fold descends vertically by the side of the posterior mediastinum to the Diaphragm. This fold is the broad ligament of the lung, the ligamentum latum pulmonis, and serves to retain the lower part of that organ in position. From the root the pleura may be traced over the convex surface of the lung, the summit and base, and also over the sides of the fissures between the lobes on to its anterior surface and the front part of its root; from this it is reflected upon the side of the pericardium to the inner surface of the sternum. Below, it covers the upper surface of the Diaphragm, and extends in front as low as the costal cartilage of the seventh rib; at the side of the chest, as low as the tenth rib on the left side and the ninth on the right side; and behind, it reaches as low as the twelfth rib, and sometimes even beyond it, as low as the transverse process of the first lumbar vertebra. Above, its apex projects, in the form of a cul-de-sac, through the superior opening of the thorax into the neck, extending from one to two inches above the margin of the first rib, and receives the summit of the corresponding lung; this sac is strengthened, according to Dr. Sibson, by a dome-like expansion of fascia, attached in front to the posterior border of the first rib, and behind to the anterior border of the transverse process of the seventh cervical vertebra. This is covered and strengthened by a few spreading muscular fibres derived from the Scaleni muscles.

A little above the middle of the sternum, the contiguous surfaces of the two pleurae are sometimes in contact for a slight extent; but above and below this point the interval left between them forms part of the mediastinum.

The inner surface of the pleura is smooth, polished, and moistened by a serous fluid; its outer surface is intimately adherent to the surface of the lung and to the pulmonary vessels as they emerge from the pericardium; it is also adherent to the upper surface of the Diaphragm: throughout the rest of its extent it is somewhat thicker, and may be easily separated from the adjacent parts.

The right pleural sac is shorter and wider than the left.

A portion of the Diaphragm below and behind, i. e. a narrow interval around this part of its circumference, is not covered by pleura and is in direct contact with the costal parietes. Furthermore, it is to be noted that there are certain localities in the pleural sac in which the surfaces of two portions of parietal pleura are always in contact, even when the lung is in a state of complete inspiration. These localities are known as sinuses or complementary spaces. The largest and most distinct of these is the costo-phrenic sinus, which follows the line of reflection of the costal pleura on to the diaphragm.

Vessels and Nerves.—The arteries of the pleura are derived from the intercostal, the internal mammary, the musculo-phrenic, thymic, pericardiae, and bronchial. The veins correspond to the arteries. The lymphatics are very numerous. The nerves are derived from the phrenic and sympathetic (Luschka). Kölliker states that nerves accompany the ramification of the bronchial arteries in the pleura pulmonalis.

Surgical Anatomy.—In operations upon the kidney it must be borne in mind that the pleura may sometimes extend below the level of the last rib, and may therefore be opened in these operations, especially when the last rib is removed in order to give more room.

**THE MEDIASTINUM.**

The Mediastinum is the space left in the median portion of the chest by the non-approximation of the two pleure. It extends from the sternum in front to the spine behind, and contains all the viscera in the thorax excepting the lungs. The mediastinum may be divided for purposes of description into two parts—an upper portion, above the upper level of the pericardium, which is named the Superior mediastinum (Struthers); and a lower portion, below the upper level of the pericardium. This lower portion is again subdivided into three—that part
which contains the pericardium and its contents, the *middle mediastinum*; that part which is in front of the pericardium, the *anterior mediastinum*; and that part which is behind the pericardium, the *posterior mediastinum*.

**Fig. 708.**—The posterior mediastinum.

The ***superior mediastinum*** is that portion of the interpleural space which lies above the upper level of the pericardium, between the manubrium sterni in front and the upper dorsal vertebrae behind. It is bounded below by a plane passing backward from the junction of the manubrium and gladiolus sterni to the lower part of the body of the fourth dorsal vertebra. It contains the origins of the Sternohyoid and Sterno-thyroid muscles and the lower ends of the Longi colli muscles; the transverse portion of the arch of the aorta; the innominate, the thoracic portion of the left carotid and subclavian arteries; the upper half of the superior
vena cava and the innominate veins, and the left superior intercostal vein; the pneumogastric, cardiac, phrenic, and left recurrent laryngeal nerves; the trachea, oesophagus, and thoracic duct; the remains of the thymus gland and lymphatics.

The anterior mediastinum is bounded in front by the sternum, on each side by the pleura, and behind by the pericardium. Owing to the oblique position of the heart toward the left side, this space is not parallel with the sternum, but directed obliquely from above downward and to the left of the median line; it is broad below, narrow above, very narrow opposite the first segment of the gladiolus of the sternum, the contiguous surfaces of the two pleura being occasionally united over a small space. The anterior mediastinum contains the origins of the Triangularis sterni muscles, and a quantity of loose areolar tissue in which some lymphatic vessels are found ascending from the convex surface of the liver, and two or three lymphatic glands (anterior mediastinal glands).

The middle mediastinum is the broadest part of the interpleural space. It contains the heart enclosed in the pericardium, the ascending aorta, the lower half of the superior vena cava, with the vena azygos major opening into it, the bifurcation of the trachea and the two bronchi, the pulmonary artery dividing into its two branches and the right and left pulmonary veins, the phrenic nerves, and some bronchial lymphatic glands.

The posterior mediastinum is an irregular triangular space running parallel with the vertebral column; it is bounded in front by the pericardium and roots of the lungs, behind by the vertebral column from the lower border of the fourth dorsal vertebra, and on either side by the pleura. It contains the descending thoracic aorta, the greater and lesser azygos veins, the pneumogastric and splanchnic nerves, the oesophagus, thoracic duct, and some lymphatic glands.

**THE LUNGS.**

The Lungs are the essential organs of respiration; they are two in number, placed one on each side of the chest, separated from each other by the heart and
other contents of the mediastinum. Each lung is conical in shape, and presents for examination an apex, a base, two borders, and two surfaces (Fig. 710).

The apex forms a tapering cone which extends into the root of the neck about an inch to an inch and a half above the level of the first rib.

The base is broad, concave, and rests upon the convex surface of the Diaphragm; its circumference is thin, and fits into the space between the lower ribs and the costal attachment of the Diaphragm, extending lower down externally and behind than in front.

The external or thoracic surface is smooth, convex, of considerable extent, and corresponds to the form of the cavity of the chest, being deeper behind than in front.

The inner surface is concave. It presents in front a depression corresponding to the convex surface of the pericardium, and behind a deep fissure (the hilum pulmonis) which gives attachment to the root of the lung.

The posterior border is rounded and broad, and is received into the deep concavity on either side of the spinal column. It is much longer than the anterior border, and projects below between the ribs and the Diaphragm.

The anterior border is thin and sharp, and overlaps the front of the pericardium.

Each lung is divided into two lobes, an upper and lower, by a long and deep fissure which extends from the upper part of the posterior border of the organ, about three inches from its apex, downward and forward to the lower part of its anterior border. This fissure penetrates nearly to the root. In the right lung the upper lobe is partially subdivided by a second and shorter fissure which extends from the middle of the preceding, forward and slightly upward, to the anterior margin of the organ, marking off a small triangular portion, the middle lobe.
The right lung is the larger and heavier; it is broader than the left, owing to the inclination of the heart to the left side; it is also shorter by an inch, in consequence of the Diaphragm rising higher on the right side to accommodate the liver.

The Root of the Lungs.—A little above the middle of the inner surface of each lung, and nearer its posterior than its anterior border, is its root, by which the lung is connected to the heart and the trachea. The root is formed by the bronchial tube, the pulmonary artery, the pulmonary veins, the bronchial arteries and veins, the pulmonary plexus of nerves, lymphatics, bronchial glands, and areolar tissue, all of which are enclosed by a reflection of the pleura. The root of the right lung lies behind the superior vena cava and ascending portion of the aorta and below the vena azygos major. That of the left lung passes beneath the arch of the aorta and in front of the descending aorta; the phrenic nerve and the anterior pulmonary plexus lie in front of each, and the pneumogastric and posterior pulmonary plexus behind each.

The chief structures composing the root of each lung are arranged in a similar manner from before backward on both sides—viz. the pulmonary veins most anterior; the pulmonary artery in the middle; and the bronchus, together with the bronchial vessels, behind. From above downward, on the two sides, their arrangement differs, thus:

On the right side their position is—bronchus (undivided portion), pulmonary artery, pulmonary veins; but on the left side their position is—pulmonary artery, bronchus, pulmonary veins; this is accounted for by the bronchus being placed on a lower level on the left than on the right side, in order that it may pass under the arch of the aorta.

The weight of both lungs together is about forty-two ounces, the right lung being two ounces heavier than the left; but much variation is met with according to the amount of blood or serous fluid they may contain. The lungs are heavier in the male than in the female, their proportion to the body being in the former as 1 to 37, in the latter as 1 to 43. The specific gravity of the lung-tissue varies from 0.345 to 0.746, water being 1000.

The color of the lungs at birth is a pinkish-white; in adult life a dark slate-color, mottled in patches; and as age advances this mottling assumes a black color. The coloring matter consists of granules of a carbonaceous substance deposited in the areolar tissue near the surface of the organ. It increases in quantity as age advances, and is more abundant in males than in females. The posterior border of the lung is usually darker than the anterior.

The surface of the lung is smooth, shining, and marked out into numerous polyhedral spaces, indicating the lobules of the organ; the area of each of these spaces is crossed by numerous lighter lines.

The substance of the lung is of a light, porous, spongy texture; it floats in water and crepitates when handled, owing to the presence of air in the tissue; it is also highly elastic; hence the collapsed state of these organs when they are removed from the closed cavity of the thorax.

Structure.—The lungs are composed of an external serous coat, a subserous areolar tissue, and the pulmonary substance or parenchyma.

The serous coat is the visceral layer of the pleura.

The subserous areolar tissue contains a large proportion of elastic fibres; it invests the surface of the lung, and extends inward between the lobules.

The parenchyma is composed of lobules which, although closely connected together by an interlobular areolar tissue, are quite distinct from one another, and may be teased asunder without much difficulty in the fovea. The lobules vary in size; those on the surface are large, of pyramidal form, the base turned toward the surface; those in the interior, smaller and of various forms. Each lobule is composed of one of the ramifications of a bronchial tube and its terminal air-cells, and of the ramifications of the pulmonary and bronchial vessels, lymphatics, and nerves, all of these structures being connected together by areolar tissue.

The bronchus, upon entering the substance of the lung, divides and subdivides
dichotomously, or rather bipinnately, throughout the entire organ. Sometimes
three branches arise together, and occasionally small lateral branches are given off
from the sides of a larger. Each of the smaller subdivisions of the bronchi enters
a pulmonary lobule, and is termed a lobular bronchial tube or bronchiole. Its wall
now begins to present irregular dilatations, air-cells or alveoli, at first sparingly
and on one side of the tube only, but as it proceeds onward these dilatations
become more numerous and surround the tube on all sides, so that it loses its cylin-
drical character. The lobular bronchiole now becomes enlarged, and is known as
the atrium or alveolar passage. From the atrium are now given off in all direc-
tions somewhat elongated blind pouches (1 mm. in diameter), the infundibula.
Each infundibulum is, in its turn, closely beset with alveoli. Within the lungs
the bronchial tubes are circular, not flattened, and present certain peculiarities of
structure.

Changes in the Structure of the Bronchi.—As the bronchial tubes become
smaller and smaller the following changes take place: The cartilages consist of
thin laminae, of varied form and size, scattered irregularly along the sides of the
tube, being most distinct at the points of division of the tubes. They may be
traced into tubes the diameter of which is only one-fourth of a line. Beyond this
point the tubes are wholly membranous. The fibrous coat and the longitudinal
elastic fibres are continued into the smallest ramifications of the bronchi. The
muscular coat is disposed in the form of a continuous layer of annular fibres, which
may be traced upon the smallest bronchial tubes. The mucous membrane lines
the bronchi and its ramifications throughout, and is covered with columnar ciliated
epithelium.

In the lobular bronchial tubes and in the infundibula the following changes take
place: The muscular tissue begins to disappear; the longitudinal elastic fibres
begin to break up, so that in the infundibula they form an interlacement around
the mouths of the air-cells. The epithelium becomes non-ciliated and flattened.
This occurs gradually; thus, in the lobular bronchioles patches of non-ciliated
flattened epithelium may be found scattered amongst the columnar ciliated epithe-
lium; then these patches of non-ciliated flattened epithelium become more and
more numerous, until in the infundibula and air-cells all the epithelium is of the
non-ciliated pavement variety. In addition to these flattened cells, there are small
polygonal granular cells in the air-sacs, in clusters of two or three, between the
others.

The air-cells are small, polyhedral, recesses composed of a fibrillated connec-
tive tissue and surrounded by a few involuntary muscular and elastic fibres. Free
within their cavities are granular leucocytes, often containing carbonaceous parti-
cles. The air-cells are well seen on the surface of the lung, and vary from \( \frac{1}{200} \) th to \( \frac{1}{16} \) th of an inch in diameter, being largest on the surface at the thin borders
and at the apex, and smallest in the interior.

The pulmonary artery conveys the venous blood to the lungs; it divides into
branches which accompany the bronchial tubes, and terminates in a dense capillary
network upon the walls of the intercellular passages and air-cells. In the lung
the branches of the pulmonary artery are usually above and behind a bronchial
tube, the vein below and in front.

The pulmonary capillaries form plexuses which lie immediately beneath the
mucous membrane in the walls and septa of the air-cells and of the infundibula.
In the septa between the air-cells the capillary network forms a single layer. The
capillaries form a very minute network, the meshes of which are smaller than the
vessels themselves;\(^1\) their walls are also exceedingly thin. The arteries of neigh-
boring lobules are distinct from each other, and do not anastomose, whereas the
corresponding venous anastomosis is extremely free.

The radicles of the pulmonary veins commence in the pulmonary capillaries,
and coalesce into larger branches, which accompany the arteries and return the

\(^1\) The meshes are only 0.002'' to 0.008'' in width, while the vessels are 0.003'' to 0.005''
(Kölliker, Human Microscopic Anatomy).
oxygenated blood to the left auricle of the heart. The radicles come together in the septa between the infundibula, entirely separate from the small arterial ramifications. Those which are near the surface of the lung have an undivided course for some distance and then either unite with some deeper lying vein or form, with their companions, a wide-meshed superficial plexus.

The bronchial arteries supply blood for the nutrition of the lung: they are derived from the thoracic aorta, and, accompanying the bronchial tubes, are distributed to the bronchial glands and upon the walls of the larger bronchial tubes and pulmonary vessels. Those supplying the bronchial tubes form a capillary plexus in the muscular coat, from which branches are given off to form a second plexus in the mucous coat. This plexus in the lobular branchioles is continuous with that of the pulmonary artery, and the blood which the bronchial artery brings is thus carried back by the pulmonary vein. Others are distributed in the interlobular areolar tissue, and terminate partly in the deep, partly in the superficial, bronchial veins. Lastly, some ramify upon the surface of the lung beneath the pleura, where they form a capillary network.

The bronchial vein is formed at the root of the lung, receiving superficial and deep veins corresponding to branches of the bronchial artery. It does not, however, receive all the blood supplied by the artery, as some of it passes into the pulmonary vein. It terminates on the right side in the vena azygos major, and on the left side in the superior intercostal or left upper azygos vein. Some authorities, especially Zuckerkanndl, state that, in other parts of the lung than in the lobular branchioles, bronchial veins, even those coming from the larger bronchial tubes, join more or less freely with pulmonary veins. The intercostal arteries give small branches to the surface of the lung, by way of the ligamentum latum pulmonis. (Turner.)

The lymphatics consist of a superficial and deep set: they terminate at the root of the lung, in the bronchial glands.

Nerves.—The lungs are supplied from the anterior and posterior pulmonary plexuses, formed chiefly by branches from the sympathetic and pneumogastric. The filaments from these plexuses accompany the bronchial tubes, upon which they are lost. Small ganglia are found upon these nerves.

Surface Form.—The apex of the lung is situated in the neck, behind the interval between the two heads of origin of the Sterno-mastoid. The height to which it rises above the clavicle varies very considerably, but is generally about one inch. It may, however, extend as much as an inch and a half or an inch and three-quarters, or, on the other hand, it may scarcely project above the level of this bone. In order to mark out the anterior margin of the lung, a line is to be drawn from the apex-point, one inch above the level of the clavicle, and rather nearer the posterior than the anterior border of the Sterno-mastoid muscle, downward and inward across the sternoclavicular articulation and first piece of the sternum until it meets, or almost meets, its fellow of the other side opposite the articulation of the manubrium and cladiolus. From this point the two lines are to be drawn downward, one on either side of the mesial line and close to it, as far as the level of the articulation of the fourth costal cartilages to the sternum. From here the two lines diverge; the left is to be drawn at first passing outward with a slight inclination downward, and then taking a bend downward with a slight inclination outward to the apex of the heart, and thence to the sixth costo-chondral articulation. The direction of the anterior border of this part of the left lung is denoted with sufficient accuracy by a curved line with its convexity directed upward and outward from the articulation of the fourth, right costal cartilage of the sternum to the fifth intercostal space, an inch and a half below and three-quarters of an inch lateral to the left nipple. The continuation of the anterior border of the right lung is marked by a prolongation of its line from the level of the fourth costal cartilages vertically downward as far as the sixth, when it slopes off along the line of the sixth costal cartilage to its articulation with the rib.

The lower border of the lung is marked out by a slightly curved line with its convexity downward from the articulation of the sixth costal cartilage to its rib to the spinous process of the tenth dorsal vertebra. If vertical lines are drawn downward from the nipple, the mid-axillary line, and the apex of the scapula, while the arms are raised from the sides, they should intersect this convex line, the first about the sixth, the second at the eighth, and the third at the tenth rib. It will thus be seen that the pleura (see page 1114) extends farther down than the lung, so that it may be wounded, and a wound pass through its cavity into the Diaphragm, and even injure the abdominal viscera, without the lung being involved.

The posterior border of the lung is indicated by a line drawn from the level of the spinous

process of the seventh cervical vertebra, down either side of the spine, corresponding to the costo-vertebral joints as low as the spinous process of the tenth dorsal vertebra. The trachea bifurcates opposite the spinous process of the fourth dorsal vertebra, and from this point the two bronchi are directed outward, the right one almost horizontally, the left with a considerable inclination downward.

The position of the great fissure in the right lung may be indicated by a line drawn from the fourth dorsal vertebra round the side of the chest to the anterior margin of the lung opposite the seventh rib, and the smaller or secondary fissure by a line drawn from the preceding where it bisects the mid-axillary line to the junction of the fourth costal cartilage to the sternum. The great fissure in the left lung is a little higher, extending from the third dorsal vertebra round the side of the chest to reach the anterior margin of the lung opposite the sixth costal cartilage.

Surgical Anatomy.—The lungs may be wounded or torn in three ways: (1) By compression of the chest, without any injury to the ribs. (2) By a fractured rib penetrating the lung. (3) By stabs, gunshot wounds, etc.

The first form is very rare, and usually occurs in young children, and affects the root of the lung—i.e. the most fixed part—and thus, implicating the great vessels, is frequently fatal. Its exact mode of causation is difficult to interpret. The probable explanation is that immediately before the compression is applied a deep inspiration is taken and the lungs are fully inflated; owing then to spasm of the glottis at the moment of compression, the air is unable to escape from the lung, which is not able to recede, and consequently gives way.

In the second variety both the pleura costalis and pulmonalis must necessarily be injured, and consequently the air taken into the wounded air-cells may find its way through these wounds into the cellular tissue of the pareties of the chest. This it may do without collecting in the pleural cavity; the two layers of the pleura are so intimately in contact that the air passes straight through from the wounded lung into the subcutaneous tissue. Emphysema constitutes, therefore, the most important sign of injury to the lung in cases of fracture of the ribs. Pneumothorax, or air in the pleural cavity, is much more likely to occur in injuries to the lung of the third variety, in which cases air passes either from the wound of the lung or from external wound into the cavity of the pleura during the respiratory movements. In these cases there is generally no emphysema of the subcutaneous tissue unless the external wound is small and valvular, so that the air drawn into the wound during inspiration is then forced into the cellular tissue around during expiration because it cannot escape from the external wound. Occasionally, in wounds of the pareties of the chest, no air finds its way into the cavity of the pleura, because the lung at the time of the accident protrudes through the wound and blocks the opening. This occurs where the wound is large, and constitutes one form of hernia of the lung. Another form of hernia of the lung occurs, though very rarely, after wounds of the chest-wall, when the wound has healed and the cicatrix subsequently yields from the pressure of the viscus behind. It forms a globular, elastic, crepitating swelling, which enlarges during expiratory efforts, falls in during inspiration, and disappears on holding the breath.

THE THYROID GLAND.

The thyroid gland bears much resemblance in structure to other glandular organs, and is classified, together with the thymus, suprarenal capsules, and
in the function of respiration. It is situated at the upper part of the trachea, and consists of two lateral lobes, placed one on each side of that tube and connected together by a narrow transverse portion, the isthmus.

Its anterior surface is convex, and covered by the Sterno-hyoid, Sterno-thyroid, and Omo-hyoid muscles.

Its lateral surfaces, also convex, lie in contact with the sheath of the common carotid artery.

Its posterior surface is concave, and embraces the trachea and larynx. The posterior borders of the gland extend as far back as the lower part of the pharynx, and on the left side to the oesophagus.

The thyroid varies in weight from one to two ounces. It is larger in females than in males, and becomes slightly increased in size during menstruation. Each lobe is somewhat conical in shape, about two inches in length, and three-quarters of an inch to an inch and a quarter in breadth, the right lobe being the larger of the two.

The isthmus connects the lower third of the two lateral lobes; it measures about half an inch in breadth and the same in depth, and usually covers the second and third rings of the trachea. Its situation presents, however, many variations—a point of importance in the operation of tracheotomy. Sometimes the isthmus is altogether wanting.

A third lobe, of conical shape, called the pyramid, occasionally arises from the upper part of the isthmus or from the adjacent portion of either lobe, but most commonly the left, and ascends as high as the hyoid bone. It is occasionally quite detached, or divided into two parts, or altogether wanting.

A few muscular bands are occasionally found attached above to the body of the hyoid bone, and below to the isthmus of the gland or its pyramidal process. These form a muscle which was named by Sömmering the Levator glandulae thyroideae.

Structure.—The thyroid body is invested by a thin capsule of connective tissue which projects into its substance and imperfectly divides it into masses or lobules of irregular form and size. When the organ is cut into it is of a brownish-red color, and is seen to be made up of a number of closed vesicles containing a yellow glairy fluid and separated from each other by intermediate connective tissue.

According to Dr. Baber, who has recently published some important observations on the minute structure of the thyroid, the vesicles of the thyroid of the adult animal are generally closed cavities; but in some young animals (e.g. young dogs) the vesicles are more or less tubular and branched. This appearance he supposes to be due to the mode of growth of the gland, and merely indicating that an increase in the number of vesicles is taking place. Each vesicle is lined by a single layer of epithelium, the cells of which, though differing somewhat in shape in different animals, have always a tendency to assume a columnar form. Between the epithelial cells exists a delicate reticulum. The vesicles are of various sizes and shapes, and contain as a normal product a viscid, homogeneous, semi-fluid, slightly yellowish material which frequently contains blood, the red corpuscles of which are found in it in various stages of disintegration and decolorization, the yellow tinge being probably due to the haemoglobin, which is thus set free from the colored corpuscles. Baber has also described in the thyroid gland of the dog large round cells ("parenchymatous cells"), each provided with a single oval-shaped nucleus, which migrate into the interior of the gland-vesicles.

The capillary blood-vessels form a dense plexus in the connective tissue around the vesicles, between the epithelium of the vesicles and the endothelium of the lymph-spaces, which latter surround a greater or smaller part of the circumference of the vesicle. These lymph-spaces empty themselves into lymphatic vessels which run in the interlobular connective tissue, not uncommonly surrounding the arteries which they accompany, and communicate with a network in the capsule

---

1 "Researches on the Minute Structure of the Thyroid Gland," Phil. Trans., part iii., 1881.
of the gland. Baber has found in the lymphatics of the thyroid a viscid material which is morphologically identical with the normal constituent of the vesicle.

**Vessels and Nerves.**—The arteries supplying the thyroid are the superior and inferior thyroid, and sometimes an additional branch (thyroidea media or ima) from the innominate artery or the arch of the aorta, which ascends upon the front of the trachea. The arteries are remarkable for their large size and frequent anastomoses. The veins form a plexus on the surface of the gland and on the front of the trachea, from which arise the superior, middle, and inferior thyroid veins, the two former terminating in the internal jugular, the latter in the innominate vein. The lymphatics are numerous, of large size, and terminate in the thoracic and right lymphatic ducts. The nerves are derived from the middle and inferior cervical ganglia of the sympathetic.

**Surgical Anatomy.**—The thyroid gland is subject to enlargement, which is called goitre. This may be due to hypertrophy of any of the constituents of the gland. The simplest (parenchymatous goitre) is due to an enlargement of the follicles. The fibroid is due to increase of the interstitial connective tissue. The cystic is that form in which one or more large cysts are formed from dilatation and possibly coalescence of adjacent follicles. The pulsating goitre is where the vascular changes predominate over the parenchymatous, and the vessels of the gland are especially enlarged. Finally, there is exophthalmic goitre (Graves's disease), where there is great vascularity and often pulsation, accompanied by exophthalmos, palpitation, and rapid pulse.

For the relief of these growths various operations have been resorted to, such as injection of tincture of iodine or perchloride of iron, especially applicable to the cystic form of the disease, ligation of the thyroid arteries, excision of the isthmus, and extirpation of the whole or a part of the gland. This latter operation is one of difficulty, and when the entire gland has been removed the operation has been followed by a condition resembling myxœdema. In removing the organ great care must be taken to avoid tearing the capsule, as if this happens the gland-tissue bleeds profusely. The thyroid arteries should be ligatured before an attempt is made to remove the mass, and in ligaturing the inferior thyroids the position of the recurrent laryngeal nerve must be borne in mind, so as not to include it in the ligation.

**THE THYMUS GLAND.**

The thymus gland presents much resemblance in structure to other glandular organs, and is another of the organs which are denominated ductless glands.

The thymus gland is a temporary organ, attaining its full size at the end of the second year, when it ceases to grow, and gradually dwindles, until at puberty it has almost disappeared. If examined when its growth is most active, it will be
found to consist of two lateral lobes placed in close contact along the middle line, situated partly in the superior mediastinum, partly in the neck, and extending from the fourth costal cartilage upward as high as the lower border of the thyroid gland. It is covered by the sternum and by the origins of the Sterno-hyoid and Sterno-thyroid muscles. Below, it rests upon the pericardium, being separated from the arch of the aorta and great vessels by a layer of fascia. In the neck it lies on the front and sides of the trachea, behind the Sterno-hyoid and Sterno-thyroid muscles. The two lobes generally differ in size; they are occasionally united so as to form a single mass, and sometimes separated by an intermediate lobe. The thymus is of a pinkish-gray color, soft, and lobulated on its surfaces. It is about two inches in length, one and a half in breadth below, and about three or four lines in thickness. At birth it weighs about half an ounce.

**Structure.**—Each lateral lobe is composed of numerous lobules held together by delicate areolar tissue, the entire gland being enclosed in an investing capsule of a similar but denser structure. The primary lobules vary in size from a pin's head to a small pea, and are made up of a number of small nodules or follicles which are irregular in shape and are more or less fused together, especially toward the interior of the gland. According to Watney, each follicle consists of a medullary and cortical portion, which differ in many essential particulars from each other. The **cortical portion** is mainly composed of lymphoid cells supported by a delicate reticulum. In addition to this reticulum, of which traces only are found in the medullary portion, there is also a network of finely-branched cells which is continuous with a similar network in the medullary portion. This network forms an adventitia to the blood-vessels. In the **medullary portion** there are but few lymphoid cells, but there are, especially toward the centre, granular cells and concentric corpuscles. The granular cells are rounded or flask-shaped masses attached (often by fibrillated extremities) to blood-vessels and to newly-formed connective tissue. The concentric corpuscles are composed of a central mass consisting of one or more granular cells, and of a capsule which is formed of epithelioid cells which are continuous with the branched cells forming the network mentioned above.

Each follicle is surrounded by a capillary plexus from which vessels pass into the interior and radiate from the periphery toward the centre, and form a second zone just within the margin of the medullary portion. In the centre of the medulla there are very few vessels, and they are of minute size.
Dr. Watney has recently made the important observation that haemoglobin is found in the thymus either in cysts or in cells situated near to or forming part of the concentric corpuscles. This haemoglobin varies from granules to masses exactly resembling colored blood-corpuses, oval in the bird, reptile, and fish; circular in all mammals except in the camel. Dr. Watney has also discovered in the lymph issuing from the thymus similar cells to those found in the gland, and, like them, containing hemoglobin either in the form of granules or masses. From these facts he arrives at the physiological conclusion that the thymus is one source of the colored blood-corpuses.

**Vessels and Nerves.**—The arteries supplying the thymus are derived from the internal mammary and from the superior and inferior thyroid. The veins terminate in the left innominate vein and in the thyroid veins. The lymphatics are of large size, arise in the substance of the gland, and are said to terminate in the internal jugular vein. The nerves are exceedingly minute; they are derived from the pneumogastric and sympathetic. Branches from the descendens hypoglossi and phrenic reach the investing capsule, but do not penetrate into the substance of the gland.
THE URINARY ORGANS.

THE KIDNEYS.

The Kidneys, two in number, are situated in the back part of the abdomen, and are for the purpose of separating from the blood certain materials which, when dissolved in a quantity of water, also separated from the blood by the kidneys, constitute the urine.

They are placed in the loins, one on each side of the vertebral column, behind the peritoneum, and surrounded by a mass of fat and loose areolar tissue. Their upper extremity is on a level with the upper border of the twelfth dorsal vertebra, their lower extremity on a level with the third lumbar. The right kidney is usually on a slightly lower level than the left, probably on account of the vicinity of the liver.

The kidneys rest on the lower part of the Diaphragm and the fascia covering the Quadratus lumborum and the Psoas magnus muscles. The right is covered in front by right lobe of liver, peritoneum intervening, the descending portion of the duodenum, and the beginning of the transverse colon; the left has in front the fundus of the stomach, the tail of the pancreas, and the descending colon (upper part).

Each kidney is about four inches in length, two to two and a half in breadth, and rather more than one inch in thickness. The left is somewhat longer, though narrower, than the right. The weight of the kidney in the adult male varies from 4½ ounces to 6 ounces, in the adult female from 4 ounces to 5½ ounces. The combined weight of the two kidneys in proportion to the body is about 1 in 240.

The kidney has a characteristic form. It is flattened and presents at one part of its circumference a hollow. It is larger at its upper than at its lower extremity. It has two surfaces, two borders, and an upper and lower extremity.

Its anterior surface is convex, looks forward and outward, and is covered by peritoneum. The upper part of this surface on the right side is in contact with the under surface of the right lobe of the liver, on which it produces a slight concave impression, the impressio renalis; below this the descending portion of the duodenum and the hepatic flexure of the colon are connected to this surface, the former by areolar tissue and the latter by its mesocolon. On the left side the upper part of the anterior surface of the kidney (covered by peritoneum of lesser sac) is in contact with the under surface of the stomach, and below this with the left extremity of the pancreas, whilst the lower part has anteriorly the splenic flexure of the colon, and internally the last portion of the duodenum.

The posterior surface is flatter than the anterior, and is imbedded in areolar tissue, which separates it from the Diaphragm and from the anterior lamella of the lumbar fascia covering the Quadratus lumborum and Psoas magnus muscle. It is also in relation with the last dorsal, ilio-inguinal, and ilio-hypogastric nerves.

The external border is convex, and is directed outward and backward. On the left side it is in contact, at its upper half or more, with the spleen, and below with the descending colon. On the right side, upper two-thirds, liver; below, ascending colon.

The internal border is concave, and is directed forward and a little downward. It presents a deep longitudinal fissure bounded by prominent anterior and posterior lip. This fissure is the hilum, and allows of the passage of the vessels, nerves, and ureter.

The superior extremity, directed slightly inward as well as upward, is thick.
and rounded, and is surmounted by the suprarenal capsule, which covers also a small portion of the anterior surface.

The inferior extremity, directed a little outward as well as downward, is smaller and thinner than the superior. It extends to within two inches of the crest of the ilium.

At the hilum of the kidney the relative position of the main structures passing into and out of the kidney is as follows: the vein is in front, the artery in the middle, and the duct or ureter behind and toward the lower part. By a knowledge of these relations the student may distinguish between the right and left kidney. The kidney is to be laid on the table before the student on its posterior surface, with its lower extremity toward the observer—that is to say, with the ureter behind and below the other vessels; the hilum will then be directed to the side to which the kidney belongs.

General Structure of the Kidney.—The kidney is surrounded by a distinct investment of fibrous tissue which forms a firm, smooth covering to the organ. It closely invests it, but can be easily stripped off, in doing which, however, numerous fine processes of connective tissue and small blood-vessels are torn through. Beneath this coat a thin wide-meshed network of unstriped muscular fibre forms an incomplete covering to the organ. When the fibrous coat is stripped off, the surface of the kidney is found to be smooth and even and of a deep-red color.

In infants fissures extending for some depth may be seen on the surface of the organ, a remnant of the lobular construction of the gland. The kidney is dense in texture, but is easily lacerable by mechanical force. In order to obtain a knowledge of the structure of the gland, a vertical section must be made from its convex to its concave border, and the loose tissue and fat removed from around the vessels and the excretory duct (Fig. 716). It will be then seen that the kidney consists of a central cavity surrounded at all parts but one by the proper kidney-substance. This central cavity is called the sinus, and is lined by a prolongation of the fibrous coat of the kidney, which enters through a longitudinal fissure, the hilum (before mentioned), which is situated at that part of the cavity which is not surrounded by kidney-structure. Through this fissure the blood-vessels of the kidney and its excretory duct pass, and therefore these structures, upon entering the kidney, are contained within the sinus. The excretory duct, or ureter, after entering, dilates into a wide, funnel-shaped sac named the pelvis. This divides into two or three tubular divisions, which subdivide into several short, truncated branches named calices or infundibula, all of which are contained in the central cavity of the kidney. The blood-vessels of the kidney, after passing through the hilum, are contained in the sinus or central cavity, lying between its lining membrane and the excretory apparatus, before entering the kidney-substance.

This central cavity, as before mentioned, is surrounded on all sides except at the hilum by the substance of the kidney, which is at once seen to consist of two parts—viz. of an external granular investing part, which is called the cortical portion; and of an internal part, the medullary portion, made up of a number of dark-colored pyramidal masses, with their bases resting on the cortical part and their apices converging toward the centre, where they form prominent papillae which project into the interior of the calices.
THE KIDNEYS.

The cortical substance is of a bright reddish-brown color, soft, granular, and easily lacerable. It is found everywhere immediately beneath the capsule, and is seen to extend in an arched form over the base of each medullary pyramid. The part separating the sides of any two pyramids through which the arteries and nerves enter, and the veins and lymphatics emerge, from the kidney, is called a cortical column or column of Bertin (A, A', Fig. 716); whilst that portion which stretches from one cortical column to the next, and intervenes between the base of the pyramid and the capsule (marked by the dotted line from A to A' in Fig. 716), is called a cortical arch, the depth of which varies from a third to half an inch.

The medullary substance, as before stated, is seen to consist of pale red-colored, striated, conical masses, the pyramids of Malpighi, the number of which, varying from eight to eighteen, correspond to the number of lobes of which the organ in the fetal state is composed. The base of each pyramid is surrounded by a cortical arch, and directed toward the circumference of the kidney; the sides are contiguous with the cortical columns; whilst the apex, known as the papilla or mammilla of the kidney, projects into one of the calices of the ureter, one calyx receiving two or three papille.

These two parts, cortical and medullary, so dissimilar in appearance, are very similar in structure, being made up of urinary tubes and blood-vessels united and bound together by a connecting matrix or stroma.

Minute Anatomy.—The tubuli uriniferi, of which the kidney is for the most part made up, commence in the cortical portion of the kidney, and, after pursuing a very circuitous course through the cortical and medullary parts of the kidney, finally terminate at the apices of the Malpighian pyramids by open mouths (Fig. 717), so that the fluid which they contain is emptied into the dilated extremity of the ureter contained in the sinus of the kidney. If the surface of one of the papillae is examined with a lens, it will be seen to be studded over with a number of small depressions from sixteen to twenty in number, and in a fresh kidney, upon pressure being made, fluid will be seen to exude from these depressions. They are the orifices of the tubuli uriniferi, which terminate in this situation. They commence in the cortical portion of the kidney as the Malpighian bodies, which are small rounded masses, varying in size, but of an average of about \( \frac{1}{12} \) of an inch in diameter. They are of a deep-red color, and are found only in the cortical portion of the kidney. Each of these little bodies is composed of two parts—a central glomerulus of vessels, called a Malpighian tuft, and a membranous envelope, the Malpighian capsule, or capsule of Bowman, which latter is a small pouch-like commencement of a uriniferous tubule.

The Malpighian tuft, or vascular glomerulus, is a network of convoluted capillary blood-vessels held together by scanty connective tissue and grouped into from two to five lobules. This capillary network is derived from a small arterial twig, the afferent vessel, which pierces the wall of the capsule, generally at a point opposite that at which the latter is connected with the tube; and the resulting vein, the efferent vessel, emerges from the capsule at the same point. The afferent vessel is usually the larger of the two (Fig. 718). The Malpighian or Bowman’s capsule, which surrounds the glomerulus, is formed of a hyaline membrane supported by a small amount of connective tissue which is continuous with the connective tissue of the tube. It is lined on its inner surface by a layer of squa-
mous epithelial cells which are reflected from the lining membrane on to the glomerulus at the point of entrance or exit of the afferent and efferent vessels. The whole surface of the glomerulus is covered with a continuous layer of the same cells on a delicate supporting membrane, which with the cells dips in between the lobules of the glomerulus, closely surrounding them (Fig. 719). Thus, between the glomerulus and the capsule a space is left, forming a cavity lined by a con-

The tubuli uriniferi, commencing in the Malpighian bodies, in their course present many changes in shape and direction, and are contained partly in the medullary and partly in the cortical portions of the organ. At their junction with the Malpighian capsule they present a somewhat constricted portion which is termed the neck. Beyond this the tube becomes convoluted, and pursues a considerable course in the cortical structure, constituting the proximal convoluted tube. After a time the convolutions disappear, and the tube approaches the medullary portion of the kidney in a more or less spiral manner. This section of the tube has been called the spiral tube of Schachova. Throughout this portion of their course the tubuli uriniferi have been contained entirely in the cortical structure, and have presented a pretty uniform calibre. They now enter the medullary portion, and suddenly become much smaller, quite straight in direction, and dip down for a variable depth into the pyramids, constituting the descending limb of Henle's loop. Bending on themselves, they form a kind of loop, the loop of Henle, and, reascending, become suddenly enlarged and again spiral in direction, forming the ascending limb of Henle's loop, and re-enter the cortical structure. This portion of the tube does not present a uniform calibre, but becomes narrower as it ascends and irregular in outline. As a narrow tube it now is found in the cortex along the medullary ray and ascends for a short distance, when it again becomes dilated, irregular, and angular, and leaves the medullary ray to enter the labyrinth of the cortex. This section is termed the irregular tubule; it terminates in a convoluted tube which exactly resembles the proximal convoluted tubule, and is called the distal convoluted tubule. This again terminates in a narrow curved or junctional tube, which enters the straight or collecting tube.

Each straight, otherwise called a collecting or receiving, tube commences by a small orifice on the summit of one of the papillae, thus opening and discharging its contents into the interior of one of the calices. Traced into the substance of the pyramid, these tubes are found to run from apex to base, dividing dichotomously in their course and slightly diverging from each other. Thus dividing and subdividing, they reach the base of the pyramid, and enter the cortical structure greatly increased in number. Upon entering the cortical portion they continue a straight course for a variable distance, and are arranged in groups called medullary rays, several of these groups corresponding to a single pyramid. The tubes in the

![Fig. 718.—Minute structure of kidney.](image)

![Fig. 719.—Malpighian body.](image)
centre of the group are the longest, and reach almost to the surface of the kidney, while the external ones are shorter, and advance only a short distance into the
cortex. In consequence of this arrangement the cortical portion presents a number of conical masses, the apices of which reach the periphery of the organ, and the bases are applied to the medullary portion. These are termed the pyramids of Ferrein. As they run through the cortical portion the straight tubes receive on either side the curved extremity of the convoluted tubes, which, as stated above, commence at the Malpighian bodies. The portions of the cortex between the medullary rays are known as the labyrinth of the cortex.

It will be seen from the above description that there is a continuous series of tubes from their commencement in the Malpighian bodies to their termination at the orifices on the apices of the pyramids of Malpighi, and that the urine, the secretion of which commences in the capsule, finds its way through these tubes into the calices of the kidney, and so into the ureter. To recapitulate: the tube first presents a constricted portion, (1) the neck. 2. It forms a wide convoluted tube, the proximal convoluted tube. 3. It becomes spiral, the spiral tubule of Schachowa. 4. It enters the medullary structure as a narrow, straight tube, the descending limb of Henle's loop. 5. Forming a loop and becoming dilated, it ascends somewhat spirally, and, gradually diminishing in calibre, again enters the cortical structure, the ascending limb of Henle's loop. 6. It now becomes irregular and angular in outline, the irregular tubule. 7. It then becomes convoluted, the distal convoluted tubule. 8. Diminishing in size, it forms a curve, the curved tubule. 9. Finally, it joins a straight tube, the straight collecting tube, which is continued downward through the medullary substance to open at the apex of a pyramid.

The Tubuli Uriniferi: their Structure.—The tubuli uriniferi consist of base-
membrane lined with epithelium. The epithelium varies considerably in different sections of the uriniferous tubes. In the neck the epithelium is continuous with that lining the Malpighian capsule, and, like it, consists of flattened cells with an oval nucleus (Fig. 720 A). The cells are, however, very indistinct and difficult to trace, and the tube has here the appearance of a simple basement membrane unlined by epithelium. In the proximal convoluted tubule and the spiral tubule of Schachowa the epithelium is polyhedral in shape, the sides of the cells not being straight, but fitting into each other, and in some animals so fused together that it is impossible to make out the lines of junction. In the human kidney the cells often present an angular projection of the surface next the basement membrane. These cells are made up of more or less rod-like fibres, which rest by one extremity on the basement membrane, whilst the other projects toward the lumen of the tube. This gives to the cells the appearance of distinct striation (Heidenhain) (Fig. 720 b). In the descending limb of Henle's loop the epithelium resembles that found in the Malpighian capsule and the commencement of the tube, consisting of flat transparent epithelial plates with an oval nucleus (Figs. 720 a, 721). In the ascending limb, on the other hand, the cells partake more of the character of those described as existing in the proximal convoluted tubule, being polyhedral in shape and presenting the same appearance of striation. The nucleus, however, is not situated in the centre of the cell, but near the lumen (Fig. 720 c). After the ascending limb of Henle's loop becomes narrower upon entering the cortical structure, the striation appears to be confined to the outer part of the cell; at all events, it is much more distinct in this situation, the nucleus, which appears flattened and angular, being still situated near the lumen (Fig. 720 d). In the irregular tubule the cells undergo a still farther change, becoming very angular, and presenting thick bright rods or markings, which render the striation much more distinct than in any other section of the urinary tubules (Fig. 720 h). In the distal convoluted tubule the epithelial cells are long in shape, are highly refractive, and their nuclei are comparatively large. In other respects they resemble those in the proximal convoluted tubule (Fig. 720 b). In the curved tubule, just before its entrance into the straight collecting tube, the epithelium varies greatly as regards the shape of the cells, some being angular with short processes, others spindle-shaped, others polyhedral (Fig. 720 e).

In the straight tubes the epithelium is more or less columnar; in its papillary portion the cells are distinctly columnar and transparent (Figs. 722, 723), but as the tube approaches the cortex the cells are less uniform in shape; some are polyhedral, and others angular with short processes (Fig. 720 f and g).

1 From the Handbook for the Physiological Laboratory.
The Renal Blood-vessels.—The kidney is plentifully supplied with blood by the renal artery, a large offset of the abdominal aorta. Previously to entering

the kidney, each artery divides into four or five branches, which are distributed to its substance. At the hilum these branches lie between the renal vein and ureter, the vein being usually in front, the ureter behind. Each vessel gives off some small branches to the suprarenal capsules, the ureter, and the sur-

rounding cellular tissue and muscles. Frequently there is a second renal artery, which is given off from the abdominal aorta at a lower level, and supplies the lower portion of the kidney. It is termed the inferior renal artery. The branches of the renal artery whilst in the sinus give off a few twigs for the nutrition of the surrounding tissues, and terminate in the arteriae propriae renales, which enter the kidney proper in the columns of Bertin. Two of these pass to each pyramid of Malpighi and run along its sides for its entire length,
giving off as they advance the afferent vessels of the Malpighian bodies in the columns. Having arrived at the bases of the pyramids, they make a bend in their course, so as to lie between the bases of the pyramids and the cortical arches, where they break up into two distinct sets of branches devoted to the supply of the remaining portions of the kidney.

The first set, the interlobular arteries (Figs. 724, 725 b), are given off at right angles from the side of the arteria propria renales looking toward the cortical substance, and, passing directly outward between the pyramids of Ferrein, they reach the capsule, where they terminate in the capillary network of this part. In their outward course they give off lateral branches; these are the afferent vessels for the Malpighian bodies (see page 1130), and, having pierced the capsule, end in the Malpighian tufts. From each tuft the corresponding renal efferent arises, and, having made its egress from the capsule near to the point where the afferent vessel entered, anastomoses with other efferents from other tufts, and contributes to form a dense venous plexus around the adjacent urinary tubes (Fig. 726).

The second set of branches from the arteria propria renales are for the supply of the medullary pyramids, which they enter at their bases; and, passing straight through their substance to their apices, terminate in the venous plexuses found in that situation. They are called the arteriole recta (Figs. 724, 725 e).

The Renal Veins arise from three sources—the veins beneath the capsule, the plexuses around the tubuli contorti in the cortical arches, and the plexuses situated at the apices of the pyramids of Malpighi. The veins beneath the capsule are stellate in arrangement, and are derived from the capillary network of the capsule, into which the terminal branches of the interlobular arteries break up. These join to form the venae interlobulares, which pass inward between the pyramids of Ferrein, receive branches from the plexuses around the tubuli contorti, and, having arrived at the bases of the Malpighian pyramids, join with the vena recta, next to be described (Figs. 724, 725 b).

The Vena Recta are branches from the plexuses at the apices of the medullary pyramids, formed by the terminations of the arteriole rectae. They pass outward in a straight course between the tubes of the medullary structure, and joining, as above stated, the venae interlobulares, form the proper renal veins (Figs. 724, 725 f).

These vessels, Vene Propria Renales, accompany the arteries of the same name, running along the entire length of the sides of the pyramids; and, having received in their course the efferent vessels from the Malpighian bodies in the cortical structure adjacent, quit the kidney substance to enter the sinus. In this cavity they inosculate with the corresponding veins from the other pyramids to form the renal vein, which emerges from the kidney at the hilum and opens into the inferior venae cava, the left being longer than the right, from having to cross in front of the abdominal aorta.

Nerves of the Kidney.—The nerves of the kidney, although small, are about fifteen in number. They have small ganglia developed upon them, and are derived from the renal plexus, which is formed by branches from the solar plexus, the lower and outer part of the semilunar ganglion and aortic plexus, and from the lesser and smallest splanchnic nerves. They communicate with the spermatic plexus, a circumstance which may explain the occurrence of pain in the testicle in affections of the kidney. So far as they have been traced, they seem to accompany
THE KIDNEYS.

1135

the renal artery and its branches, but their exact mode of termination is not known.

The lymphatics consist of a superficial and deep set which terminate in the lumbar glands.

Connective Tissue, or Intertubular Stroma.—Although the tubules and vessels are closely packed, a certain small amount of connective tissue, continuous with the capsule, binds them firmly together. This tissue was first described by Goodsir, and subsequently by Bowman. Ludwig and Zawarykin have observed distinct fibres passing around the Malpighian bodies, and Henle has seen them between the straight tubes composing the medullary structure.

Surface Form.—The kidneys, being situated at the back part of the abdominal cavity and deeply placed, cannot be felt unless enlarged or misplaced. They are situated on the confines of the epigastric and umbilical regions internally, with the hypochondriac and lumbar regions externally. The left is somewhat higher than the right. According to Morris, the position of the kidney may be thus defined: Anteriorly: "1. A horizontal line through the umbilicus is below the lower edge of each kidney. 2. A vertical line carried upward to the costal arch from the middle of Poupart's ligament has one-third of the kidney to its outer side and two-thirds to its inner side—i.e. between this line and the median line of the body." In adopting these lines it must be borne in mind that the axes of the kidneys are not vertical, but oblique, and if continued upward would meet about the ninth dorsal vertebra. Posteriorly: The upper end of the left kidney would be defined by a line drawn horizontally outward from the spinous process of the eleventh dorsal vertebra, and its lower end by a point two inches above the iliac crest. The right kidney would be half to three-quarters of an inch lower. Morris lays down the following rules for indicating the position of the kidney on the posterior surface of the body: "1. A line parallel with, and one inch from, the spine, between the lower edge of the tip of the spinous process of the eleventh dorsal vertebra and the lower edge of the spinous process of the third lumbar vertebra. 2. A line from the top of this first line outward at right angles to it for 2½ inches. 3. A line from the lower end of the first transversely outward for 2½ inches. 4. A line parallel to the first and connecting the outer extremities of the second and third lines just described."

The hilum of the kidney lies about two inches from the middle line of the back, at the level of the spinous process of the first lumbar vertebra.

Surgical Anatomy.—The kidney is imbedded in a large quantity of loose fatty tissue, and is but slightly covered by peritoneum; hence rupture of this organ is not nearly so serious an accident as rupture of the liver or spleen, since the extravasation of blood and urine which follows is outside the peritoneal cavity. Occasionally the kidney may be bruised by blows in the loin or by being compressed between the lower ribs and the ilium when the body is violently bent forward. This is followed by a little transient hematuria, which, however, speedily passes off. Occasionally, when rupture involves the pelvis of the kidney or the commencement of the ureter, this duct may become blocked, and hydronephrosis follow.

The loose cellular tissue around the kidney may be the seat of suppuration, constituting perinephritic abscess. This may be due to injury, to disease of the kidney itself, or to extension of inflammation from neighboring parts. It may burst into the pleura, constituting empyema; into the colon or bladder; or may point externally in the groin or loin. Tumors of the kidney, of which renal sarcoma in children is the most common, may be recognized by their position and fixity; by the resonant colon lying in front of it; by their not moving with respiration; and by their rounded outline, not presenting a notched anterior margin like the spleen, with which they are most likely to be confounded. The examination of the kidney should be bimanual; that is to say, one hand should be placed in the flank and firm pressure made forward, while the other hand is buried in the abdominal wall just external to the semilunar line. Manipulation of the kidney frequently produces a peculiar sickening sensation, with sometimes faintness.

The kidney is mainly held in position by the mass of fatty matter in which it is imbedded and over which the peritoneum is stretched. If this fatty matter is loose or lax or is absorbed, the kidney may become movable and may give rise to great pain. This condition occurs, therefore, in badly-nourished people or in those who have become emaciated from any cause, and is more common in women than in men. It must not be confounded with the floating kidney: this is a congenital condition due to the development of a meso-nephron, which permits the organ to move more or less freely. The two conditions cannot, however, be distinguished until the abdomen is opened or the kidney explored from the loin.

The kidney has, of late years, been frequently the seat of surgical interference. It may be exposed for exploration or the evacuation of pus (nephrotyotomy); it may be incised for the removal of stone (nephro-lithotomy); it may be sutured when movable or floating (nephorrhaphy); or it may be removed (nephrectomy).

The kidney may be exposed either by a lumbar or abdominal incision. The lumbar operation is the more which is generally adopted, unless in cases of very large tumors or of wandering kidneys, in which a lumbar incision is inadequate. Many of the advantages of not opening the peritoneum and of affording admirable drainage may be performed either by an oblique, a vertical, or a transverse incision. Perhaps the preferable, as affording the best
means for exploring the whole surface of the kidney, is an incision from the tip of the last rib backward to the edge of the Erector spine. This incision must not be quite parallel to the rib, but its posterior end must be at least three-quarters of an inch below it, lest the pleura be wounded. This cut is quite sufficient for an exploration of the organ. Should it require removal, a vertical incision can be made downward to the crest of the ilium, along the outer border of the Quadratus lumborum. The structures divided are the skin, the superficial fascia with the cutaneous nerves, the deep fascia, the posterior border of the External oblique muscle of the abdomen, and the outer border of the Latissimus dorsi; the Internal oblique and the posterior aponeurosis of the Transversalis muscle; the outer border of the Quadratus lumborum, and the deep layer of the transversalis aponeurosis, and the transversalis fascia. The fatty tissue around the kidney is now exposed to view, and must be separated by the fingers or a director in order to reach the kidney.

The abdominal operation is best performed by an incision in the linea semilunaris on the side of the kidney to be removed, as recommended by Langenbuch. The incision is made of varying length according to the size of the kidney; its mid-point should be on a level with the umbilicus. The abdominal cavity is opened. The intestines are then held aside and the outer layer of the meso-colon opened, so that the fingers can be introduced behind the peritoneum and the renal vessels sought for. These are then to be ligatured; if tied separately, care must be taken to ligature the artery first. The kidney must now be enucleated, and the vessels and ureter divided, and the latter tied or, if thought necessary, stitched to the edge of the wound.

THE URETERS.

The Ureters are the two tubes which conduct the urine from the kidneys into the bladder. They commence within the sinus of the kidney by a number of short truncated branches, the calices or infundibula, which unite either directly or indirectly to form a dilated pouch, the pelvis, from which the ureter, after passing through the hilum of the kidney, descends to the bladder. The calices are cup-like tubes encircling the apices of the Malpighian pyramids; but inasmuch as one calyx may include two or even more papillae, their number is generally less than the pyramids themselves, the former being from seven to thirteen, whilst the latter vary from eight to eighteen. These calices converge into two or three tubular divisions which by their junction form the pelvis or dilated portion of the ureter. The portion last mentioned, where the pelvis merges into the ureter proper, is found opposite the spinous process of the first lumbar vertebra, in which situation it is accessible behind the peritoneum.

The ureter proper is a cylindrical membranous tube, about sixteen inches in length and of the diameter of a goosequill, extending from the pelvis of the kidney to the bladder. Its course is obliquely downward and inward through the lumbar region into the cavity of the pelvis, where it passes downward, forward, and inward across that cavity to the base of the bladder, into which it then opens by a constricted orifice, after having passed obliquely for nearly an inch between its muscular and mucous coats.

Relations.—In its course it rests upon the Psoas muscle, being covered by the peritoneum, and crossed obliquely, from within outward, by the spermatic vessels; the right ureter lying close to the outer side of the inferior vena cava. Opposite the first piece of the sacrum it crosses either the common or external iliac artery, lying behind the ilium on the right side and the sigmoid flexure of the colon on the left. In the pelvis it enters the posterior false ligament of the bladder below the obliterated hypogastric artery, the vas deferens in the male passing between it and the bladder. In the female the ureter passes along the side of the cervix of the uterus and upper part of the vagina. At the level of the external os it is three-fifths of an inch external to the cervix, and is crossed by the uterine artery, a venous plexus intervening (Holl). At the base of the bladder it is situated about two inches from its fellow, lying, in the male, about an inch and a half behind the prostate.

Structure.—The ureter has three coats—a fibrous, muscular, and mucous. The fibrous coat is the same throughout the entire length of the duct, being continuous at one end with the capsule of the kidney at the floor of the sinus, whilst at the other it is lost in the fibrous structure of the bladder.

In the pelvis of the kidney the muscular coat consists of two layers, longitudinal and circular: the longitudinal fibres become lost upon the sides of the papillae at
THE SUPRARENAL CAPSULES.

The extremities of the calices; the circular fibres may be traced surrounding the medullary structure in the same situation. In the ureter proper the muscular fibres are very distinct, and are arranged in three layers—an external longitudinal, a middle circular, and an internal layer, less distinct than the other two, but having a general longitudinal direction. According to Kölliker, this internal layer is only found in the neighborhood of the bladder.

The mucous coat is smooth, and presents a few longitudinal folds which become effaced by distension. It is continuous with the mucous membrane of the bladder below, whilst it is prolonged over the papillae of the kidney above. Its epithelium is of a peculiar character, and resembles that found in the bladder. It is known by the name of "transitional" epithelium. It consists of several layers of cells, of which the innermost—that is to say, the cells in contact with the urine—are quadrilateral in shape, with a concave margin on their outer surface, into which fits the rounded end of the cells of the second layer. These, the intermediate cells, more or less resemble columnar epithelium, and are pear-shaped, with a rounded internal extremity which fits into the concavity of the cells of the first layer, and a narrow external extremity which is wedged in between the cells of the third layer. The external or third layer consists of conical or oval cells varying in number in different parts, and presenting processes which extend down into the basement membrane.

The arteries supplying the ureter are branches from the renal, spermatic, internal iliac, and inferior vesical.

The nerves are derived from the inferior mesenteric, spermatic, and pelvic plexuses.

THE SUPRARENAL CAPSULES.

The Suprarenal Capsules are classified, together with the spleen, thymus, and thyroid, under the head of "ductless glands," as they have no excretory duct. They are two small flattened glandular bodies, of a yellowish color, situated at the back part of the abdomen, behind the peritoneum and immediately above and a little in front of the upper part of each kidney; hence their name. The right one is somewhat triangular in shape, bearing a resemblance to a cocked hat; the left is more semilunar, and usually larger and higher than the right. They vary in size in different individuals, being sometimes so small as to be scarcely detected; their usual size is from an inch and a quarter to nearly two inches in length, rather less in width, and from two to three lines in thickness. Their average weight is about a drachm each.

Relations.—The relations of the suprarenal capsules differ on the two sides of the body. The right suprarenal presents on its anterior surface two areas: along its upper and inner borders a depressed area, which is in contact in front with the under surface of the right lobe of the liver, and along its inner border with the inferior vena cava (Rolleston), and behind rests on the crus of the Diaphragm; over the remainder of the anterior surface is an elevated area, which is covered in front by peritoneum passing from the upper part of the kidney to the under surface of the liver, and behind rests on the upper and inner part of the kidney. The left suprarenal is in contact by its anterior surface, superiorly, with the spleen; below and internal to this it is in contact with the peritoneum forming the lesser sac, which separates it from the cardiac extremity of the stomach; and at its lower part it is covered by the pancreas and splenic artery, and is therefore not in contact with the peritoneum. By its posterior surface, at its outer and back part, it rests upon the kidney, whilst below and internally it is in contact with the left crus of the Diaphragm.

Structure.—The surface of the suprarenal gland is surrounded by areolar tissue containing much fat, and closely invested by a thin fibrous coat, which is difficult to remove on account of the numerous fibrous processes and vessels which enter the organ through the furrows on its anterior surface and base.

Small accessory suprarenals are often to be found in the connective tissue
THE URINARY ORGANS.

around the suprarenals. The smaller of these, on section, show a uniform surface, but in some of the larger a distinct medulla can be made out.

On making a perpendicular section, the gland is seen to consist of two substances—external or cortical and internal or medullary. The former, which constitutes the chief part of the organ, is of a deep-yellow color. The medullary substance is soft, pulpy, and of a dark-brown or black color, whence the name atrabiliary capsules formerly given to these organs. In the centre is often seen a space, not natural, but formed by the breaking down after death of the medullary substance.

The cortical portion consists chiefly of narrow columnar masses placed perpendicularly to the surface. This arrangement is due to the disposition of the capsule, which sends into the interior of the gland processes passing in vertically and communicating with each other by transverse bands so as to form spaces which open into each other. These spaces are of slight depth near the surface of the organ, so that, there the section somewhat resembles a net; this is termed the zona glomerulosa; but they become much deeper or longer farther in, so as to resemble pipes or tubes placed endwise, the zona fasciculata. Still deeper down, near the medullary part, the spaces become again of small extent; this is named the zona reticularis. These processes or trabeculae, derived from the capsule and forming the framework of the spaces, are composed of fibrous connective tissue with longitudinal bundles of unstriped muscular fibres. Within the interior of the spaces are contained groups of polyhedral cells, which are finely granular in appearance, and contain a spherical nucleus, and not unfrequently fat-molecules. These groups of cells do not entirely fill the spaces in which they are contained,
but between them and the trabeculae of the framework is a channel which is believed to be a lymph-path or sinus, and which communicates with certain passages between the cells composing the group. The lymph-path is supposed to open into a plexus of efferent lymphatic vessels which are contained in the capsule.

In the medullary portion the fibrous stroma seems to be collected together into a much closer arrangement, and forms bundles of connective tissue which are loosely applied to the large plexus of veins of which this part of the organ mainly consists. In the interstices lie a number of cells compared by Frey to those of columnar epithelium. They are coarsely granular, do not contain any fat-molecules, and some of them are branched. Luschka has affirmed that these branches are connected with the nerve-fibres of a very intricate plexus which is found in the medulla: this statement has not been verified by other observers, for the tissue of the medullary substance is less easy to make out than that of the cortical, owing to its rapid decomposition.

The numerous arteries which enter the suprarenal bodies from the sources mentioned below penetrate the cortical part of the gland, where they break up into capillaries in the fibrous septa, and these converge to the very numerous veins of the medullary portion, which are collected together into the suprarenal vein, which usually emerges as a single vessel from the centre of the gland.

The arteries supplying the suprarenal capsules are numerous and of large size: they are derived from the aorta, the phrenic, and the renal; they subdivide into numerous minute branches previous to entering the substance of the gland.

The suprarenal vein returns the blood from the medullary venous plexus, and receives several branches from the cortical substance; it opens on the right side into the inferior vena cava, on the left side into the renal vein.

The lymphatics terminate in the lumbar glands.

The nerves are extremely numerous: they are found chiefly, if not entirely, in the medulla, and are derived from the solar and renal plexuses, and, according to Bergmann, from the phrenic and pneumogastric nerves. They have numerous small ganglia developed upon them, from which circumstance the organ has been conjectured to have some function in connection with the sympathetic nervous system.

THE CAVITY OF THE PELVIS.

The cavity of the pelvis is that part of the general abdominal cavity which is below the level of the linea ilio-pectinea and the promontory of the sacrum.

Boundaries.—It is bounded behind by the sacrum, the coccyx, the Pyriformis muscle, and the great sacro-sciatic ligaments; in front and at the sides by the osa pubis and ischia, covered by the Obturator muscles; above, it communicates with the cavity of the abdomen; and below, the outlet is closed by the triangular ligament, the Levatores ani and Coccygei muscles, and the visceral layer of the pelvic fascia, which is reflected from the wall of the pelvis on to the viscera.

Contents.—The viscera contained in this cavity are—the urinary bladder, the rectum, and some of the generative organs peculiar to each sex, and some convolutions of the small intestines; they are partially covered by the peritoneum, and supplied with blood-vessels, lymphatics, and nerves.

THE BLADDER.

The bladder is the reservoir for the urine. It is a musculo-membranous sac situated in the pelvis, behind the pubes, and in front of the rectum in the male, the cervix uteri and upper part of the vagina intervening in the female. The shape, position, and relations of the bladder are greatly influenced by age, sex, and the degree of distention of the organ. During infancy it is conical in shape, and projects above the upper border of the os pubis into the hypogastric region. In the adult, when quite empty and contracted, it, together with the urethra, in a median
vertical section, is Y-shaped, the urethra forming the stem of the Y. It is placed deeply in the pelvis, flattened from before backward, the anterior limb of the Y reaching as high as the upper border of the symphysis pubis. When slightly distended it has a rounded form, and is still contained within the pelvic cavity; and when fully distended it is ovoid in shape, and rises into the abdominal cavity. When greatly distended it may reach nearly as high as the umbilicus. It is larger in its vertical diameter than from side to side, and its long axis is directed from above obliquely downward and backward, in a line directed from some point between the os pubis and umbilicus (according to its distention) to the end of the coccyx. The bladder, when distended, is slightly curved forward toward the anterior wall of the abdomen, so as to be more convex behind than in front. In the female it is larger in the transverse than in the vertical diameter, and its capacity is

said to be greater than in the male.\(^1\) When moderately distended it contains about a pint.

The bladder has a \textit{summit} and five surfaces, \textit{superior} or abdominal, \textit{postero-inferior} or base, \textit{antero-inferior} or pubic, and two \textit{lateral} or sides.

The \textit{summit} or apex of the bladder looks forward and upward; it is connected to the abdominal wall by a fibro-muscular cord, the \textit{urachus}, which is the obliterated remains of a tubular canal which, in the embryo, prolongs the cavity of the bladder into the \textit{allantois}. It passes upward from the apex of the bladder between the transversalis fascia and peritoneum to the umbilicus, becoming thinner as it ascends. On each side of it is placed a fibrous cord, the obliterated portion of the hypogastric artery, which, passing upward from the side of the bladder, approaches the urachus above its summit. In the infant, at birth, the urachus is sometimes found per-

\(^1\) According to Henle, the bladder is considerably smaller in the female than in the male.
vious, so that the urine escapes at the umbilicus, and calculi have been found in its canal.

The superior or abdominal surface is free, and extends antero-posteriorly from the summit to the base; laterally, it reaches to the sides of the bladder from which it is approximately marked off by the obliterated hypogastric arteries. This surface is entirely covered by peritoneum, and is in relation with the uterus, in the female, the sigmoid flexure, in the male, and in either sex with some loops of the small intestine. Posteriorly on each side, beneath the peritoneum, is, in the male, a part of the vas deferens.

The antero-inferior or pubic surface is not covered in front by peritoneum, but is in relation with the triangular ligament, the posterior surface of the symphysis pubis, the anterior parts of Levator ani and Internal obturator muscles,

and, when distended, with the abdominal parietes, recto-vesical fascia being interposed.

The side of the bladder is crossed obliquely from below, upward and forward, by the obliterated hypogastric artery; above and behind this cord the side of the bladder is covered by peritoneum, but below and in front of it the serous covering is wanting, and it is connected to the recto-vesical fascia. The vas deferens passes, in an arched direction, from before backward, along the posterior portion (sub-peritoneal) of the side of the bladder, toward its base, crossing the obliterated hypogastric artery, and passing along the inner side of the ureter. The space occupied by recto-vesical fascia, which lies between the pubic surface and those portions of the sides of the bladder which are uncovered by peritoneum on the one hand, and their antero-inferior relations on the other, is known as the Cavum Retzii or space of Retzius.
The base (fundus) of the bladder is directed downward and backward. It varies in extent according to the state of distention of the organ, being very broad when full, but much narrower when empty. In the male it rests upon the second portion of the rectum, from which it is separated by a reflection of the recto-vesical fascia. It is covered superiorly, for a slight extent, by the peritoneum, which is reflected from it upon the rectum, forming the recto-vesical fold. The portion of the bladder in relation with the rectum corresponds to a triangular space bounded in front by the prostate gland, and on each side by the vesicula seminalis and vas deferens. In the female the base of the bladder lies in contact with the cervix uteri and upper part of the anterior wall of the vagina. Above this connection is the peritoneal utero-vesical pouch.

The so-called neck of the bladder is the point of commencement of the urethra. The portion of the bladder immediately surrounding it is in relation with the prostate gland.

Ligaments.—The bladder is retained in its place by ligaments which are divided into true and false. The true ligaments are five in number: two anterior, two lateral, and the urachus. The false ligaments, also five in number, are formed by folds of the peritoneum.

The anterior ligaments (pubo-prostatic) extend from the back of the os pubis, one on each side of the symphysis, to the pubic surface of the bladder, over the upper surface of the prostate gland. These ligaments are formed by the recto-vesical fascia, and contain muscular fibres prolonged from the bladder.
The lateral ligaments, also formed by the recto-vesical fascia, are broader and thinner than the preceding. They are attached to the lateral parts of the prostate and to the sides of the bladder and the pelvic wall. The posterior prolongation of this ligament is known as the ligament of the rectum.

The urachus is the fibro-muscular cord already mentioned, extending between the summit of the bladder and the umbilicus. It is broad below, and becomes narrower as it ascends.

The false ligaments of the bladder are—two posterior, two lateral, and one superior.

The two posterior pass forward, in the male, from the sides of the rectum; in the female, from the sides of the uterus to the posterior and lateral aspect of the bladder; they form the lateral boundaries of the recto-vesical cul-de-sac of the peritoneum, and contain the obliterated hypogastric arteries and the ureters, together with vessels and nerves.

The two lateral ligaments are reflections of the peritoneum from the iliac fossae to the sides of the bladder, along the line of the obliterated hypogastric arteries.

The superior ligament is the prominent fold of the peritoneum extending from the summit of the bladder to the umbilicus. It covers the urachus and the obliterated hypogastric arteries.

Structure.—The bladder is composed of four coats—serous, muscular, submucous, and mucous.

The serous coat is derived from the peritoneum. It invests the entire superior surface, the upper part of the base, and each side, above and behind the "hypogastric cord," and is reflected on to the abdominal and pelvic walls.

The muscular coat consists of three layers of unstripped muscular fibre: an external layer, composed of fibres having for the most part a longitudinal arrangement; a middle layer, in which the fibres are arranged, more or less, in a circular manner; and an internal layer, in which the fibres have a general longitudinal arrangement.

The fibres of the external longitudinal layer arise from the posterior surface of the body of the os pubis in both sexes (musculi pubo-vesicalis), and in the male from the adjacent part of the prostate gland and its capsule. They pass, in a more or less longitudinal manner, up the anterior surface of the bladder, over its apex, and then descend along its posterior surface to its base, where they become attached to the prostate in the male and to the front of the vagina in the female. At the sides of the bladder the fibres are arranged obliquely and intersect one another. This layer has been named the detrusor urinæ muscle.

The middle circular layers are very thinly and irregularly scattered on the body of the organ, and, though to some extent placed transversely to the long axis of the bladder, are for the most part arranged obliquely. Toward the lower part of the bladder, round the cervix and commencement of the urethra, they are dispersed in a thick circular layer, forming the sphincter vesicae, which is continuous with the muscular fibres of the prostate gland.

The internal longitudinal layer is thin, and its fasciculi have a reticular arrangement, but with a tendency to assume for the most part a longitudinal direction.

Two bands of oblique fibres, originating behind the orifices of the ureters, pass between these orifices and also converge to the back part of the prostate gland, and are inserted, by means of a fibrous process, into the middle lobe of that organ. They are the muscles of the ureters, described by Sir C. Bell, who supposed that during the contraction of the bladder they served to retain the oblique direction of the ureters, and so prevent the reflux of the urine into them.

The submucous coat consists of a layer of areolar tissue connecting together the muscular and mucous coats, and intimately united to the latter.

The mucous coat is thin, smooth, and of a pale rose color. It is continuous through the ureters with the lining membrane of the uriniferous tubes, and below with that of the urethra. It is connected loosely to the muscular coat by a layer
of areolar tissue, excepting at the trigone, where its adhesion is more close. It is provided with mucous follicles, more numerous than elsewhere near the neck of the organ, but which are not regarded as definite glands. The epithelium covering it is of the transitional stratified variety, consisting of a superficial layer of polyhedral, flattened cells, each with one, two, or three nuclei; beneath these a stratum of large club-shaped cells, with the narrow extremity directed downward and wedged in between smaller spindle-shaped cells, containing an oval nucleus (Figs. 733, 734).

**Objects Seen on the Inner Surface.**—Upon the inner surface of the bladder are seen the orifices of the ureters, the trigone, and the orifice of the urethra.

**The Orifices of the Ureters.**—These are situated at each end of the base of the trigone, being distant from each other by less than two inches; they are about an inch and a half from the base of the prostate and the commencement of the urethra.

The *trigonum vesice* (Lieutaud), or *trigone vesicale*, is a triangular smooth surface, with the apex directed forward, situated in the base of the bladder immediately behind the urethral orifice. It is paler in color than the rest of the mucous membrane, and never presents any rugue, even in the collapsed condition of the organ, owing to its intimate adhesion to the subjacent tissue. It is bounded at each posterior angle by the orifice of the ureter. Its antero-inferior angle is occupied by the orifice of the urethra. Between the orifices of the ureters is seen an arched fold (*plica ureterica*) of mucous membrane caused by the projection of muscular fibres which have a similar direction (see preceding page). Projecting from the lower and anterior part and reaching to the orifice of the urethra is a slight elevation of mucous membrane called the *uvula vesicae*. It is formed by a thickening of the submucous tissue. In the female, the uvula vesicæ and trigonum are small and ill-defined.

The arteries supplying the bladder are the superior, middle, and inferior vesical in the male, with additional branches from the uterine and vaginal in the female. They are all derived from the anterior trunk of the internal iliac. The obturator and sciatic arteries also supply small vesical branches to the bladder.

The veins form a complicated plexus round the neck, sides, and base of the bladder, and terminate in the internal iliac vein.

The lymphatics accompany the blood-vessels, passing through the glands surrounding them.

The nerves are derived from the pelvic plexus of the sympathetic and from the third and the fourth sacral nerves; the former supplying the upper part of the organ, the latter its base and neck. According to F. Darwin, the sympathetic fibres have ganglia connected with them, which send branches to the vessels and muscular coat.

**Surface Form.**—The surface form of the bladder varies with its degree of distension and under other circumstances. In the young child it is represented by a conical figure, the apex
of which, even when the viscus is empty, is situated in the hypogastric region, about an inch above the level of the symphysis pubis. In the adult, when the bladder is empty, its apex does not reach above the level of the upper border of the symphysis pubis, and the whole organ is situated in the pelvis; the neck, in the male, corresponding to a line drawn horizontally backward through the symphysis a little below its middle. As the bladder becomes distended it gradually rises out of the pelvis into the abdomen, and forms a swelling in the hypogastric region which is perceptible to the hand as well as to percussion. In extreme distension it reaches into the umbilical region. Under these circumstances it is closely applied to the abdominal wall, without the intervention of peritoneum, so that it can be tapped by an opening in the middle line just above the pubes without any fear of wounding the serous membrane. When the rectum is distended the prostatic portion of the urethra is elongated and the bladder lifted out of the pelvis and the peritoneum pushed upward. Advantage is taken of this in performing the operation of suprapubic cystotomy. The rectum is distended by an india-rubber bag, which is introduced into this cavity empty, and then filled with ten or twelve ounces of water. If now the bladder is injected with about half a pint of some antiseptic fluid, it will appear above the pubes, plainly perceptible to the sight and touch. The peritoneum will be pushed out of the way, and an incision three inches long may be made in the linea alba from the symphysis pubis upward without any great risk of wounding the peritoneum.

When distended the bladder can be felt in the male from the rectum, behind the prostate, and fluctuation can be perceived by a bimanual examination, one finger being introduced into the rectum and the distended bladder tapped on the front of the abdomen with the finger of the other hand. This portion of the bladder—that is, the portion felt in the rectum by the finger—is also uncovered by peritoneum, and the bladder may here be punctured from the rectum, in the middle line, without risk of wounding the serous membrane.

**Surgical Anatomy.**—A defect of development in which the bladder is implicated is known under the name of **extroversion of the bladder.** In this condition the lower part of the abdominal wall and the anterior wall of the bladder are wanting, so that the posterior surface of the bladder presents on the abdominal surface, and is pushed forward by the pressure of the viscera within the abdomen, forming a red vascular tumor on which the openings of the ureters are visible. The penis, except the glans, is rudimentary and is cleft on its dorsal surface, exposing the floor of the urethra—a condition known as **epiploitis.** The pelvic bones are also arrested in development (see page 283).

The bladder may be ruptured by violence applied to the abdominal wall, when the viscus is distended without any injury to the bony pelvis, or it may be torn in cases of fracture of the pelvis. The rupture may be either intraperitoneal or extraperitoneal—that is, may implicate the superior surface of the bladder in the former case, or one of the other surfaces in the latter. Rupture of the anterior surface alone is, however, very rare. Until recently intraperitoneal rupture was uniformly fatal, but now abdominal section and suturing the rent with Lembert’s suture is resorted to, with a very considerable amount of success. The sutures are inserted only through the peritoneal and muscular coats in such a way as to bring the serous surfaces at the margins of the wound into apposition, and one is inserted just beyond the end of the wound. The bladder should be tested as to whether it is water-tight before closing the external wound.

The muscular coat of the bladder undergoes hypertrophy in cases in which there is any obstruction to the flow of urine. Under these circumstances the bundles of which the muscular coat consists become much increased in size, and, interlacing in all directions, give rise to what is known as the **fasciculated bladder.** Between these bundles of muscular fibres the mucous membrane bulge out, forming sacculi, constituting the **sacculated bladder,** and in these little pouches phosphatic secretions may collect, forming **encysted calculus.** The mucous membrane is very loose and lax, except over the trigone, to allow of the distension of the viscus.

Various forms of tumor have been found springing from the wall of the bladder. The
innocent tumors are the papilloma and the mucous polypus, arising from the mucous membrane; the fibrous, from the submucous tissue; and the myoma, originating in the muscular tissue; and, very rarely, dermoid tumors, the exact origin of which it is difficult to explain. Of the malignant tumors, epitheloma is the most common, but sarcomata are occasionally found in the bladder of children.

Puncture of the bladder may be performed either above the pubes or through the rectum, in both cases without wounding the peritoneum. The former plan is generally to be preferred, since in puncture by the rectum a permanent fistula may be left from abscess forming between the rectum and the bladder; or pelvic cellulitis may be set up; moreover, it is exceedingly inconvenient to keep a cannula in the rectum. In some cases in performing this operation the recto-vesical pouch of peritoneum has been wounded, inducing fatal peritonitis. The operation, therefore, has been almost completely abandoned.

**THE MALE URETHRA.**

The urethra in the male extends from the neck of the bladder to the meatus urinarius. It presents a double curve in the flaccid state of the penis, but in the erect state it forms only a single curve, the concavity of which is directed upward (Fig. 599). Its length varies from eight to nine inches, and it is divided into three portions, the prostatic, membranous, and spongy, the structure and relations of which are essentially different. Except during the passage of the urine or semen the urethra is a mere transverse cleft or slit, with its upper and under surfaces in contact. At the orifice of the urethra at the end of the penis the slit is vertical, and in the prostatic portion somewhat arched.

The Prostatic Portion is the widest and most dilatable part of the canal. It passes through the prostate gland, from its base to its apex, lying nearer its upper than its lower surface. It is about an inch and a quarter in length; the form of the canal is spindle-shaped, being wider in the middle than at either extremity, and narrowest in front, where it joins the membranous portion. A transverse section of the canal as it lies in the prostate is horseshoe in shape, the convexity being directed upward (Fig. 736) or rather forward, since its direction is nearly vertical.

Upon the floor of the canal is a narrow longitudinal ridge, the verumontanum, or colliculus seminalis, or caput gallinaginis, formed by an elevation of the mucous membrane and its subjacent tissue. It is eight or nine lines in length and a line and a half in height, and contains, according to Kobelt, muscular and erectile tissues. When distended it may serve to prevent the passage of the semen backward into the bladder. On each side of the verumontanum is a slightly depressed fossa, the prostatic sinus, the floor of which is perforated by numerous apertures, the orifices of the prostatic duets, the ducts of the middle lobe opening behind the verumontanum. At the fore part of the verumontanum, in the middle line, is a depression, the sinus pocularis (vesicula prostatica), and upon or within its margins are the slit-like openings of the ejaculatory ducts. The sinus pocularis forms a cul-de-sac about a quarter of an inch in length, which runs upward and backward in the substance of the prostate beneath the middle lobe; its prominent upper wall partly forms the verumontanum. Its walls are composed of fibrous tissue, muscular fibres, and mucous membrane, and numerous small glands open on its inner surface. It has been called by Weber, who discovered it, the uterus masculinus, from its being developed from the united ends of the rudimentary Müllerian ducts, and therefore homologous with the uterus in the female.

The Membranous portion of the urethra extends between the apex of the prostate and the bulb of the corpus spongiosum. It is the narrowest part of the canal (excepting the orifice), and measures three-quarters of an inch along its anterior and half an inch along its posterior surface, in consequence of the bulb projecting backward beneath it. Its anterior concave surface is placed about an inch beneath the pubic arch, from which it is separated by the dorsal vessels and nerves of the penis and some muscular fibres. Its posterior convex surface is separated from the rectum by a triangular space, which is part of the perineum. The membranous portion of the urethra perforates both the anterior and posterior layers of the deep perineal fascia, and receives an investment from them. As it pierces the posterior layer, the fibres around the opening are prolonged backward.
over the posterior part of the membranous portion of the urethra, and as it pierces the anterior layer, a similar prolongation takes place in the opposite direction, investing the anterior part of the membranous portion. It is also surrounded by the Compressor urethrae muscle.

The **Spongy portion** is the longest part, and is contained in the corpus spongiosum. It is about six inches in length, and extends from the termination of the membranous portion of the meatus urinarius. Its direction at first is downward and forward then upward for a short distance and then downward again. It is narrow and of uniform size, in the body of the penis, measuring about a quarter of an inch in diameter, being dilated behind, within the bulb, and again anteriorly within the glans penis, where it forms the fossa navicularis.

The **Bulbous portion** is a name given, in some descriptions of the urethra, to the posterior part of the spongy portion contained within the bulb.

The **meatus urinarius** is the most contracted part of the urethra; it is a vertical slit, about three lines in length, bounded on each side by two small labia.

The inner surface of the lining membrane of the urethra, especially on the floor of the spongy portion, presents the orifices of numerous mucous glands and follicles situated in the submucose tissue, and named the glands of Liittré. They vary in size, and their orifices are directed forward, so that they may easily intercept the point of a catheter in its passage along the canal. One of these lacunae, larger than the rest, is situated in the upper surface of the fossa navicularis, about an inch and a half from the orifice; it is called the lacuna magna. Into the bulbous portion are found opening the ducts of Cowper’s glands.

**Structure.**—The urethra is composed of a continuous mucous membrane, supported by a submucose tissue which connects it with the various structures through which it passes.

The **mucous coat** forms part of the genito-urinary mucous membrane. It is continuous with the mucous membrane of the bladder, ureters, and kidneys; externally with the integument covering the glans penis; and is prolonged into the ducts of the glands which open into the urethra—viz. Cowper’s glands and the prostate gland—and into the vasa deferentia and vesicule seminales through the ejaculatory ducts. In the spongy and membranous portions the mucous membrane is arranged in longitudinal folds when the organ is contracted. Small papillae are found upon it near the orifice, and its epithelial lining is of the columnar and stratified variety, excepting near the meatus, where it is squamous.

The **submucous tissue** consists of a vascular erectile layer, outside which is a layer of unstripped muscular fibres, arranged in a circular direction, which separates the mucous membrane and submucose tissue from the tissue of the corpus spongiosum.

**Surgical Anatomy.**—The urethra may be ruptured by the patient falling astride of any hard substance and striking his perineum, so that the urethra is crushed against the pubic arch. Bleeding will at once take place from the urethra, and this, together with the bruising in the perineum and the history of the accident, will at once point to the nature of the injury.

The surgical anatomy of the urethra is of considerable importance in connection with the passage of instruments into the bladder. Otis was the first to point out that the urethra is capable of great dilatability, so that, excepting through the external meatus, an instrument corresponding to 18 English gauge (20 French) can usually be passed without damage. The orifice of the urethra is not so dilatable, and therefore frequently requires slitting. A recognition of this dilatability caused Bigelow to very considerably modify the operation of lithotomy and introduce that of litholapaxy. In passing catheters, especially fine ones, the point of the instrument should be kept as far as possible along the upper wall of the canal, as the point is otherwise very liable to enter one of the lacunae. Stricture of the urethra is a disease of very common occurrence, and is generally situated in the spongy portion of the urethra, most commonly in the bulbous portion, just in front of the membranous urethra, but in a very considerable number of cases in the penile or ante-scrotal part of the canal.
MALE GENERATIVE ORGANS.

THE PROSTATE GLAND.

The prostate gland (προστατή, to stand before) is a firm, muscular, glandular body, which is placed immediately in front of the neck of the bladder and around the commencement of the urethra. It is placed in the pelvic cavity, behind and below the symphysis pubis, posterior to the deep perineal fascia, and rests upon the rectum, through which it may be distinctly felt, especially when enlarged. In shape and size it is said to resemble a chestnut.

Its base is directed upward and backward and rests against the neck of the bladder.

Its apex is directed downward and forward to the deep perineal fascia, which it touches.

Its posterior surface is smooth and flat, marked by a slight longitudinal furrow, and rests on the rectum, to which it is connected by dense areolar tissue.

Its anterior surface is convex, and is placed about three-quarters of an inch behind the lower part of the pubic symphysis.

It measures about an inch and a half in its transverse diameter at the base, an inch in its antero-posterior diameter, and three-quarters of an inch in depth. Its weight is about five drachms. It is held in its position by the anterior ligaments of the bladder (pubo-prostatic); by the posterior layer of the deep perineal fascia, which invests the commencement of the membranous portion of the urethra and

Fig. 736.—Transverse section of normal prostate through the middle of the verumontanum, from a subject aged nineteen years. (Taylor.) a, Longitudinal sections of ducts leading from the lobules of the prostatic glands; b, verumontanum; c, sinus pocusolaris; d, urethra; e, ejaculatory ducts; f, arteries, veins, and venous sinuses in capsule of prostate; g, nerve trunks in capsule; h, point of origin of fibro-muscular bands encircling urethra; i, zone of striated voluntary muscle on superior surface. (Drawn from Erdninger projection apparatus.)
prostate gland; and by the anterior portion of the Levator ani muscle (levator prostate), which passes down on each side from the symphysis pubis and anterior ligament of the bladder to the sides of the prostate.

The prostate consists of two lateral lobes and a middle lobe.

The two lateral lobes are of equal size, separated by a deep notch behind, and by a slight furrow upon the anterior and posterior surfaces of the gland, which indicates the bilobed condition of the organ in some animals.

The third, or middle lobe, is a small transverse band, occasionally a rounded or triangular prominence, placed between the two lateral lobes at the posterior part of the organ. It lies immediately beneath the neck of the bladder, behind the commencement of the urethra, and above and between the ejaculatory ducts. Its existence is not constant, but it is occasionally found at an early period of life, as well as in adults and in old age.

The prostate gland is perforated by the urethra and the ejaculatory ducts. The urethra usually lies about one-third nearer its posterior than its anterior surface; occasionally, the prostate surrounds only the lower three-fourths of the tube, and more rarely the urethra runs through the lower instead of the upper part of the gland. The ejaculatory ducts pass forward obliquely between the middle and each lateral lobe of the prostate and open into the prostatic portion of the urethra.

Structure.—The prostate is enclosed in a thin but firm fibrous capsule, distinct from that derived from the posterior layer of the deep perineal fascia, and separated from it by a plexus of veins. Its substance is of a pale reddish-gray color, of great density and not easily torn. It consists of glandular substance and muscular tissue.

The muscular tissue, according to Kölliker, constitutes the proper stroma of the prostate, the connective tissue being very scanty, and simply forming thin trabeculae between the muscular fibres, in which the vessels and nerves of the gland ramify. The muscular tissue is arranged as follows: Immediately beneath the fibrous capsule is a dense layer, which forms an investing sheath for the gland; secondly, around the urethra, as it lies in the prostate, is another dense layer of circular fibres, continuous behind with the internal layer of the muscular coat of the bladder, and in front blending with the fibres surrounding the membranous portion of the urethra. Between these two layers strong bands of muscular tissue, which decussate freely, form meshes in which the glandular structure of the organ is imbedded. In that part of the gland which is situated above the urethra the muscular tissue is especially dense, and there is here little or no gland tissue; while in that part which is below the urethra the muscular tissue presents a wide-meshed structure, which is densest at the upper part of the gland—that is, near the bladder—becoming looser and more sponge-like toward the apex of the organ.

The glandular substance is composed of numerous follicular pouches, opening into elongated canals, which join to form from twelve to twenty small excretory ducts. The follicles are connected together by areolar tissue, supported by prolongations from the fibrous capsule and muscular stroma, and enclosed in a delicate capillary plexus. The epithelium lining of both the canals and the terminal vesicles is of the columnar variety. The prostatic ducts open into the floor of the prostatic portion of the urethra.

Vessels and Nerves.—The arteries supplying the prostate are derived from the internal pudic, vesical, and haemorrhoidal. Its veins form a plexus around the sides and base of the gland; they receive in front the dorsal vein of the penis, and terminate in the internal iliac vein. The nerves are derived from the pelvic plexus.

Surgical Anatomy.—The relation of the prostate to the rectum should be noted: by means of the finger introduced into the gut the surgeon detects enlargement or other disease of this organ; he can feel the apex of the gland, which is the guide to Cock's operation for stricture; he is enabled also by the same means to direct the point of a catheter when its introduction is attended with difficulty either from injury or disease of the membranous or prostatic portions of
the urethra. When the finger is introduced into the bowel the surgeon may, in some cases, especially in boys, learn the position, as well as the size and weight, of a calculus in the bladder; and in the operation for its removal, if, as is not unfrequently the case, it should be lodged behind an enlarged prostate, it may be displaced from its position by pressing upward the base of the bladder from the rectum. The prostate gland is occasionally the seat of suppuration, either due to injury, gonorrhoea, or tuberculous disease. The gland, being enveloped in a dense unyielding capsule, determines the course of the abscess, and also explains the great pain which is present in the acute form of the disease. The abscess most frequently bursts into the urethra, the direction in which there is least resistance, but may occasionally burst into the rectum, or more rarely in the perineum. In advanced life the prostate becomes considerably enlarged, and projects into the bladder so as to impede the passage of the urine. According to Dr. Messer’s researches, conducted at Greenwich Hospital, it would seem that such obstruction exists in 20 per cent. of all men over sixty years of age. In some cases the enlargement affects principally the lateral lobes, which may undergo considerable enlargement without causing much inconvenience. In other cases it would seem that the middle lobe enlarges most, and even a small enlargement of this lobe may act injuriously, by forming a sort of valve over the urethral orifice, preventing the passage of the urine, and blocking more completely the orifice the more the patient strains. In consequence of the enlargement of the prostate a pouch is formed at the base of the bladder behind the projection, in which water collects and cannot be entirely expelled. It becomes decomposed and ammoniacal, and leads to cystitis. For this condition “prostatectomy” is sometimes done. The bladder is opened by an incision above the symphysis pubis, the mucous membrane incised, and the enlarged and projecting middle lobe enucleated.

COWPER’S GLANDS.

Cowper’s Glands are two small rounded and somewhat lobulated bodies of a yellow color, about the size of peas, placed behind the fore part of the membranous portion of the urethra, between the two layers of the deep perineal fascia. They lie close above the bulb, and are enclosed by the transverse fibres of the Compressor urethrae muscle. Their existence is said to be constant: they gradually diminish in size as age advances.

Structure.—Each gland consists of several lobules held together by a fibrous investment. Each lobule consists of a number of acini lined by columnar epithelial cells, opening into one duct, which, joining with the ducts of other lobules outside the gland, form a single excretory duct. The excretory duct of each gland, nearly an inch in length, passes obliquely forward beneath the mucous membrane, and opens by a minute orifice on the floor of the bulbous portion of the urethra. Their existence is said to be constant; they gradually diminish in size as age advances.

THE PENIS.

The Penis is the organ of copulation. It consists of a root, body, and extremity, or glans penis.

The root is firmly connected to the rami of the os pubis and ischium by two strong tapering, fibrous processes, the crura, and to the front of the symphysis pubis by the suspensory ligament, a strong band of fibrous tissue which passes downward from the front of the symphysis pubis to the upper surface of the root of the penis, where it blends with the fascial sheath of the organ.

The extremity or glans penis, presents the form of an obtuse cone, flattened from above downward. At its summit is a vertical fissure, the orifice of the urethra (meatus urinarius). The base of the glans forms a rounded projecting border, the corona glandis, and behind the corona is a deep constriction, the cervix. Upon both of these parts numerous small sebaceous glands are found, the glandulae Tysonii odoriferae. They secrete a sebaceous matter of very peculiar odor, which probably contains casein and becomes easily decomposed.

The body of the penis is the part between the root and extremity. In the flaccid condition of the organ it is cylindrical, but when erect has a triangular prismatic form with rounded angles, the broadest side being turned upward, and called the dorsum. The body is covered by integument, and contains in its interior a large portion of the urethra. The integument covering the penis is remarkable for its thinness, its dark color, its looseness of connection with the deeper parts of the organ, and its containing no adipose tissue. At the root of the penis the
integument is continuous with that upon the pubes and scrotum, and at the neck of the glans it leaves the surface and becomes folded upon itself to form the prepuce.

The internal layer of the prepuce is attached behind to the cervix, and approaches in character to a mucous membrane; from the cervix it is reflected over the glans penis, and at the meatus urinarius is continuous with the mucous lining of the urethra.

The mucous membrane covering the glans penis contains no sebaceous glands, but projecting from its free surface are a number of small, highly sensitive papillae. At the back part of the meatus urinarius a fold of mucous membrane passes backward to the bottom of a depressed raphe, where it is continuous with the prepuce; this fold is termed the *frénum praéputii*.

**Structure of the Penis.**—The penis is composed of a mass of erectile tissue enclosed in three cylindrical fibrous compartments. Of these, two, the *corpora cavernosa*, are placed side by side along the upper part of the organ; the third, or *corpus spongiosum*, encloses the urethra and is placed below.

The *Corpora Cavernosa* form the chief part of the body of the penis. They consist of two fibrous cylindrical tubes, placed side by side, and intimately connected along the median line for their anterior three-fourths, whilst at their back part they separate from each other to form the *crura*, which are two strong tapering fibrous processes firmly connected to the rami of the os pubis and ischium. Each crus commences by a blunt-pointed process in front of the tuberosity of the ischium, and before its junction with its fellow to form the body of the penis it presents a slight enlargement, named by Kobelt the *bulb of the corpus cavernosus*. Just beyond this point they become constricted, and retain an equal diameter to their anterior extremity, where they form a single rounded end which is received into a fossa in the base of the glans penis. A median groove on the upper surface lodges the dorsal vein of the penis, and the groove on the under surface receives the corpus spongiosum. The root of the penis is connected to the symphysis pubis by the suspensory ligament.

**Structure.**—The corpora cavernosa are surrounded by a strong fibrous envelope, consisting of two sets of fibres—the one, longitudinal in direction, being common to the two corpora cavernosa, and investing them in a common covering; the other, internal, being circular in direction, and being proper to each corpus cavernosum. The internal circular fibres by their junction at one part form an incomplete partition or septum between the two bodies.

The *septum* between the two corpora cavernosa forms an imperfect partition; it is thick and complete behind, but in front it is incomplete, and consists of a number of vertical bands, which are arranged like the teeth of a comb, whence the name which it has received. *septum pectiniforme*. These bands extend between the dorsal and the urethral surface of the corpora cavernosa. This fibrous investment is extremely dense, of considerable thickness, and consists of bundles of shining white fibres, with an admixture of well-developed elastic fibres, so that it is possessed of great elasticity.

From the internal surface of the fibrous envelope, as well as from the sides of the septum, are given off a number of bands or cords which cross the interior of the corpora cavernosa in all directions, subdividing them into a number of separate compartments, and giving the entire structure a spongy appearance. These bands and cords are called *trabeculae*, and consist of white fibrous tissue, elastic fibres, and plain muscular fibres. In them are contained numerous arteries and nerves.

The component fibres of which the trabeculae are composed are larger and stronger round the circumference than at the centre of the corpora cavernosa; they are also thicker behind than in front. The interspaces, on the contrary, are larger at the centre than at the circumference, their long diameter being directed transversely; they are largest anteriorly. They are occupied by venous blood, and are lined by a layer of flattened cells similar to the endothelial lining of veins.
The whole of the structure of the corpora cavernosa contained within the fibrous sheath consists, therefore, of a sponge-like tissue of areolar spaces freely communicating with each other and filled with venous blood. The spaces may therefore be regarded as large cavernous veins.

The arteries bringing the blood to these spaces are the arteries of the corpora cavernosa and branches from the dorsal artery of the penis, which perforate the fibrous capsule, along the upper surface, especially near the fore part of the organ.

These arteries on entering the cavernous structure divide into branches which are supported and enclosed by the trabeculae. Some of these terminate in a capillary network, the branches of which open directly into the cavernous spaces; others assume a tendril-like appearance, and form convoluted and somewhat dilated vessels, which were named by Müller helicine arteries. They project into the spaces, and from them are given off small capillary branches to supply the trabecular structure. They are bound down in the spaces by fine fibrous processes, and are more abundant in the back part of the corpora cavernosa (Fig. 737).

The blood from the cavernous spaces is returned by a series of vessels, some of which emerge in considerable numbers from the base of the glans penis and converge on the dorsum of the organ to form the dorsal vein; others pass out on the upper surface of the corpora cavernosa and join the dorsal vein; some emerge from the under surface of the corpora cavernosa, and, receiving branches from the corpus spongiosum, wind round the sides of the penis to terminate in the dorsal vein; but the greater number pass out at the root of the penis and join the prostatic plexus.

The Corpus Spongiosum encloses the urethra, and is situated in the groove on the under surface of the corpora cavernosa. It commences posteriorly in front of the deep perineal fascia, between the diverging crura of the corpora cavernosa, where it forms a rounded enlargement, the bulb, and terminates anteriorly in another expansion, the glans penis, which overlaps the anterior rounded extremity of the corpora cavernosa. The central portion, or body of the corpus spongiosum, is cylindrical, and tapers slightly from behind forward.

The bulb varies in size in different subjects; it receives a fibrous investment from the anterior layer of the deep perineal fascia, and is surrounded by the Accelerator urinae muscle. The urethra enters the bulb nearer its upper than its lower surface, being surrounded by a layer of erectile tissue, a thin prolongation of which is continued backward round the membranous and prostatic portions of the canal to the neck of the bladder, lying between the two layers of muscular tissue. The portion of the bulb below the urethra presents a partial division into two lobes, being marked externally by a linear raphe, whilst internally there projects inward, for a short distance, a thin fibrous septum, more distinct in early life.
Structure.—The corpus spongiosum consists of a strong fibrous envelope, enclosing a trabecular structure, which contains in its meshes erectile tissue. The fibrous envelope is thinner, whiter in color, and more elastic than that of the corpora cavernosa. The trabeculae are delicate, uniform in size, and the meshes between them small, their long diameter, for the most part, corresponding with that of the penis. The external envelope or outer coat of the corpus spongiosum is formed partly of unstripped muscular fibre, and a layer of the same tissue immediately surrounds the canal of the urethra.

The lymphatics of the penis consist of a superficial and deep set; the former are derived from a dense network on the skin of the glans and prepuce and from the mucous membrane of the urethra, and terminate in the superficial inguinal glands; the latter emerge from the corpora cavernosa and corpus spongiosum, and, passing beneath the pubic arch, join the deep lymphatics of the pelvis.

The nerves are derived from the internal pudic nerve and the pelvic plexus. On the glans and bulb some filaments of the cutaneous nerves have Pacinian bodies connected with them, and, according to Krause, many of them terminate in a peculiar form of end-bud.

Surgical Anatomy.—The penis occasionally requires removal for malignant disease. Usually, removal of the ante-scrotal portion is all that is necessary, but sometimes it is requisite to remove the whole organ from its attachment to the rami of the os pubis and ischium. The former operation is performed either by cutting off the whole of the anterior part of the penis with one sweep of the knife, or, what is better, cutting through the corpora cavernosa from the dorsum, and then separating the corpus spongiosum from them, dividing it at a level nearer the glans penis. The mucous membrane of the urethra is then slit up, and the edges of the flap attached to the external skin, in order to prevent contraction of the orifice, which would otherwise take place. The vessels which require ligature are the two dorsal arteries of the penis, the arteries of the corpora cavernosa, and the artery of the septum. When the entire organ requires removal the patient is placed in the lithotomy position, and an incision is made round the root of the penis, and carried down the median line of the scrotum as far as the perineum. The two halves of the scrotum are then separated from each other, and, after Rule having been introduced into the bladder as a guide, the membranous portion of the urethra is separated from the corpus spongiosum and divided. The catheter having been withdrawn, just behind the bulb. The suspensory ligament is now severed, and the scrotum separated from the bone with a periosteum scraper, and the whole penis removed. The membranous portion of the urethra, which has not been removed, is now to be attached to the skin at the posterior extremity of the incision in the perineum. The remainder of the wound is to be brought together, free drainage being provided for.

THE TESTES AND THEIR COVERINGS (Fig. 738).

The Testes are two glandular organs, which secrete the semen; they are situated in the scrotum, being suspended by the spermatic cords. At an early period of fetal life the testes are contained in the abdominal cavity, behind the peritoneum. Before birth they descend to the inguinal canal, along which they pass with the spermatic cord, and, emerging at the external abdominal ring, they descend into the scrotum, becoming invested in their course by numerous coverings derived from the serous, muscular, and fibrous layers of the abdominal parietes, as well as by the scrotum. The coverings of the testes are—the

The Scrotum is a cutaneous pouch which contains the testes and part of the spermatic cords. It is divided superficially into two lateral halves by a median line, or raphe, which is continued forward to the under surface of the penis and backward along the middle line of the perineum to the anus. Of these two lateral portions, the left is longer than the right, and corresponds with the greater length of the spermatic cord on the left side. Its external aspect varies under different circumstances:
thus, under the influence of warmth and in old and debilitated persons it becomes elongated and flaccid, but under the influence of cold and in the young and robust it is short, corrugated, and closely applied to the testes.

The scrotum consists of two layers, the integument and the dartos.

The **integument** is very thin, of a brownish color, and generally thrown into folds or rugae. It is provided with sebaceous follicles, the secretion of which has a peculiar odor, and is beset with thinly-scattered, crisp hairs, the roots of which are seen through the skin.

The **dartos** is a thin layer of loose reddish tissue, endowed with contractility: it forms the proper tunic of the scrotum, is continuous, around the base of the scrotum, with the two layers of the superficial fascia of the groin and perineum, and sends inward a distinct septum, **septum scroti**, which divides it into two cavities for the two testes, the septum extending between the raphe and the under surface of the penis as far as its root.

The dartos is closely united to the skin externally, but connected with the subjacent parts by delicate areolar tissue, upon which it glides with the greatest facility. The dartos is very vascular, and consists of a loose areolar tissue containing unstriped muscular fibre, but no fat. Its contractility is slow, and excited by cold and mechanical stimuli, but not by electricity.

The **intercolumnar fascia** is a thin membrane derived from the margin of the pillars of the external abdominal ring, during the descent of the testes in the fetus, which is prolonged downward around the surface of the cord and testis. It is separated from the dartos by loose areolar tissue, which allows of considerable movement of the latter upon it, but is intimately connected with the succeeding layers.

The **cremasteric fascia** consists of scattered bundles of muscular fibres (Cremaster muscle) connected together into a continuous covering by intermediate areolar tissue. The muscular fibres are continuous with the lower border of the Internal oblique muscle of the abdomen.

The **fascia propria** is a thin membranous layer which loosely invests the surface of the cord. It is a continuation downward of the infundibuliform process of the fascia transversalis and the subperitoneal areolar tissue, and is acquired during the descent of the testis in the fetus.
The \textit{tunica vaginalis} is described with the proper covering of the testis.

\textbf{Vessels and Nerves.}—The \textit{arteries} supplying the coverings of the testis are: the superficial and deep external pudic, from the femoral; the superficial perineal branch of the internal pudic; and the cremasteric branch from the epigastric. The \textit{veins} follow the course of the corresponding arteries. The \textit{lymphatics} terminate in the inguinal glands. The \textit{nerves} are: the ilio-inguinal branch of the lumbar plexus, the two superficial perineal branches of the internal pudic nerve, the inferior pudendal branch of the small sciatic nerve, and the genital branch of the genito-crural nerve.

The \textbf{Spermatic Cord} extends from the internal abdominal ring, where the structures of which it is composed converge, to the back part of the testicle. In the abdominal wall the cord passes obliquely along the inguinal canal, resting on Poupart’s ligament. It lies at first between the Internal oblique and the fascia transversalis; but nearer the pubes it has the aponeurosis of the External oblique in front of it and the conjoined tendon behind it. It then escapes at the external ring, and descends nearly vertically into the scrotum. The left cord is rather longer than the right, consequently the left testis hangs somewhat lower than its fellow.

\textbf{Structure of the Spermatic Cord.}—The spermatic cord is composed of arteries, veins, lymphatics, nerves, the excretory duct of the testicle, and a thin fibrous cord, the \textit{remains of the peritoneal pouch}, caused by the descent of the testicle. These structures are connected together by areolar tissue, and invested by the fasciae brought down by the testicle in its descent.

The \textit{arteries of the cord} are: the spermatic, from the aorta; the artery of the vas deferens, from the superior vesical; the cremasteric, from the deep epigastric.

The \textit{spermatic artery}, a branch of the abdominal aorta, escapes from the abdomen at the internal or deep abdominal ring, and accompanies the other constituents of the spermatic cord along the inguinal canal and through the external abdominal ring into the scrotum. It then descends to the testicle, and, becoming tortuous, divides into several branches, two or three of which accompany the vas deferens and supply the epididymis, anastomosing with the artery of the vas deferens; others pierce the back of the tunica albuginea and supply the substance of the testis.

The \textit{cremasteric artery} is a branch of the deep epigastric artery. It accompanies the spermatic cord and supplies the Cremaster muscle and other coverings of the cord, anastomosing with the spermatic artery.

The \textit{artery of the vas deferens}, a branch of the superior vesical, is a long slender vessel which accompanies the vas deferens, ramifying upon the coats of that duct, and anastomosing with the spermatic artery near the testis.

The spermatic veins emerge from the back of the testis and receive tributaries from the epididymis; they unite and form a convoluted plexus (\textit{plexus pampiniformis}), which forms the chief mass of the cord: the vessels composing this plexus are very numerous, and ascend along the cord in front of the vas deferens; below the external or superficial abdominal ring they unite to form three or four veins, which pass along the spermatic canal, and, entering the abdomen through the internal or deep abdominal ring, coalesce to form two veins. These again unite to form a single vein, which opens on the right side into the inferior vena cava at an acute angle, and on the left side into the renal vein at a right angle.

The \textit{lymphatic vessels} terminate in the lumbar glands.

The \textit{nerves} are the spermatic plexus from the sympathetic, joined by filaments from the pelvic plexus which accompany the artery of the vas deferens.

\textbf{Surgical Anatomy.}—The scrotum forms an admirable covering for the protection of the testicle. This body, lying suspended and loose in the cavity of the scrotum and surrounded by a serous membrane, is capable of great mobility, and can therefore easily slip about within the scrotum, and thus avoid injuries from blows or squeezes. The skin of the scrotum is very elastic and capable of great distension, and on account of the looseness and amount of subcutaneous tissue the scrotum becomes greatly enlarged in cases of oedema, to which this part is especially liable on account of its dependent position. The scrotum is frequently the seat of
epithelioma; this is no doubt due to the rube on its surface, which favor the lodgment of dirt, and this, causing irritation, is the exciting cause of the disease, which is especially common in chimney-sweeps from the lodgment of soot. The scrotum is also the part most frequently affected by elephantiasis.

On account of the looseness of the subcutaneous tissue considerable extravasations of blood may take place from very slight injuries. It is therefore generally recommended never to apply leeches to the scrotum, since they may lead to considerable ecchymosis, but rather to puncture one or more of the superficial veins of the scrotum in cases where local bloodletting from this part is judged to be desirable. The muscular fibre in the dartos causes contraction and considerable diminution in the size of a wound of the scrotum, as after the operation of castration, and is of assistance in keeping the edges together and covering the exposed parts.

THE TESTES.

The Testes are suspended in the scrotum by the spermatic cords. As the left spermatic cord is rather longer than the right one, the left testicle hangs somewhat lower than its fellow. Each gland is of an oval form, compressed laterally, and having an oblique position in the scrotum, the upper extremity being directed forward and a little outward, the lower, backward and a little inward; the anterior convex border looks forward, outward, and downward; the posterior or straight border, to which the cord is attached, inward, backward, and upward.

The anterior border and lateral surfaces, as well as both extremities of the organ, are convex, free, smooth, and invested by the tunica vaginalis. The posterior border, to which the cord is attached, receives only a partial investment from that membrane. Lying along this posterior border is a long, narrow, flattened body, named from its relation to the testis, the epididymis (ἐὔδομος; testis). It consists of a central portion, or body; an upper enlarged extremity, the globus major, or head; and a lower pointed extremity, the tail, or globus minor. The globus major is intimately connected with the upper end of the testicle by means of its efferent ducts, and the globus minor is connected with its lower end by cellular tissue and a reflection of the tunica vaginalis. The outer surface and upper and lower ends of the epididymis are free and covered by serous membrane; the body is also completely invested by it, excepting along its posterior border. The epididymis is connected to the back of the testis by a fold of the serous membrane. Attached to the upper end of the testis or to the epididymis are one or more small pedunculated bodies. One of them is pretty constantly found between the globus major of the epididymis and the testicle, and is believed to be the remains of the upper extremity of the Müllerian duct (page 136). It is termed the hydatid of Morgagni. When the testicle is removed from the body, the position of the vas deferens, on the posterior surface of the testicle and inner side of the epididymis, marks the side to which the gland has belonged.

Size and Weight.—The average dimensions of this gland are from one and a half to two inches in length, one inch in breadth, and an inch and a quarter in the antero-posterior diameter, and the weight varies from six to eight drachms, the left testicle being a little the larger.

The testis is invested by three tunics—the tunica vaginalis, tunica albuginea, and tunica vasculosa.

The Tunica Vaginalis is the serous covering of the testis. It is a pouch of serous membrane, derived from the peritoneum during the descent of the testis in the fetus from the abdomen into the scrotum. After its descent that portion of the pouch which extends from the internal ring to near the upper part of the gland becomes obliterated, the lower portion remaining as a shut sac, which invests the outer surface of the testis, and is reflected on to the internal surface of the scrotum; hence it may be described as consisting of a visceral and parietal portion.

The visceral portion (tunica vaginalis propria) covers the outer surface of the testis, as well as the epididymis, connecting the latter to the testis by means of a distinct fold forming a depression, the digital fossa. From the posterior border of the gland it is reflected on to the internal surface of the scrotum.
The parietal portion of the serous membrane (tunica vaginalis reflexa) is far more extensive than the visceral portion, extending upward for some distance in front and on the inner side of the cord, and reaching below the testis. The inner surface of the tunica vaginalis is free, smooth, and covered by a layer of endothelial cells. The interval between the visceral and parietal layers of this membrane constitutes the cavity of the tunica vaginalis.

The obliterated portion of the pouch may generally be seen as a fibro-cellular thread lying in the loose areolar tissue around the spermatic cord; sometimes this may be traced as a distinct band from the upper end of the inguinal canal, where it is connected with the peritoneum, down to the tunica vaginalis; sometimes it gradually becomes lost on the spermatic cord. Occasionally no trace of it can be detected. In some cases it happens that the pouch of peritoneum does not become obliterated, but the sac of the peritoneum communicates with the tunica vaginalis. This may give rise to one of the varieties of oblique inguinal hernia (page 1191). Or in other cases the pouch may contract, but not become entirely obliterated; it then forms a minute canal leading from the peritoneum to the tunica vaginalis. 1

The Tunica Albuginea is the fibrous covering of the testis. It is a dense fibrous membrane, of a bluish-white color, composed of bundles of white fibrous tissue, which interlace in every direction. Its outer surface is covered by the tunica vaginalis, except along its posterior border, at the points of attachment of the epididymis; hence the tunica albuginea may be considered as a fibro-serous membrane, like the pericardium. This membrane surrounds the glandular structure of the testicle, and at its posterior border is reflected into the interior of the gland, forming an incomplete vertical septum, called the mediastinum testis (corpus Hygromianum).

The mediastinum testis extends from the upper, nearly to the lower, border of the gland, and is wider above than below. From the front and sides of this septum numerous slender fibrous cords and imperfect septa (trabeculae) are given off, which radiate toward the surface of the organ, and are attached to the inner surface of the tunica albuginea. They therefore divide the interior of the organ into a number of incomplete spaces, which are somewhat cone-shaped, being broad at their bases at the surface of the gland, and becoming narrower as they converge to the mediastinum. The mediastinum supports the vessels and ducts of the testis in their passage to and from the substance of the gland.

The Tunica Vasculosa (pia mater testis) is the vascular layer of the testis, consisting of a plexus of blood-vessels held together by a delicate areolar tissue. It covers the inner surface of the tunica albuginea and the different septa in the interior of the gland, and therefore forms an internal investment to all the spaces of which the gland is composed.

Structure.—The glandular structure of the testis consists of numerous lobules (lobuli testis). Their number, in a single testis, is estimated by Berres at 250, and by Krause at 400. They differ in size according to their position, those in the middle of the gland being larger and longer. The lobules are conical in shape, the base being directed toward the circumference of the organ, the apex toward the

1 It is recorded that in the post-mortem examination of Sir Astley Cooper this minute canal was found on both sides of the body. Sir Astley Cooper states that when a student he suffered from inguinal hernia; probably this was of the congenital variety, and the canal found after death was the remains of the one down which the hernia travelled (Lanced, vol. ii., 1824, p. 116).
MALE GENERATIVE ORGANS.

Each lobule is contained in one of the intervals between the fibrous cords and vascular processes which extend between the mediastinum testis and the tunica albuginea, and consists of from one to three or more minute convoluted tubes, the tubuli seminiferi. The tubes may be separately unravelled by careful dissection under water, and may be seen to commence either by free excal ends or by anastomotic loops. The total number of tubes is considered by Munro to be about 300, and the length of each about sixteen feet; by Lauth their number is estimated at 840, and their average length two feet and a quarter. The diameter varies from $\frac{3}{100}$ to $\frac{1}{16}$ of an inch. The tubuli are pale in color in early life, but in old age they acquire a deep yellow tinge from containing much fatty matter. They consist of a membrana propria, inside which are several layers of epithelial cells, the seminal cells. The membrana propria is a hyaline structure, consisting of several membranous layers, containing oval flattened nuclei at regular intervals, superimposed on one another. The seminal cells or lining epithelium differ in different tubules. In some tubes they may be seen to consist of an outer layer, next the membrana propria, and two or more layers of inner cells. The former cells are more or less polyhedral in shape, uniform in size, and contain an oval or spherical nucleus; the latter cells, those comprising the inner layers, are spherical and more loosely connected together. The nucleus of most or all of them is in the process of indirect division (karyokinesis, page 40), and in consequence of this numerous small spherical daughter-cells are to be seen, lying nearest to the lumen and closely connected together. These small daughter-cells are named spermatoblasts, and by a series of changes become converted into spermatozoa. In other tubes the gradual transition of the spermatoblasts into spermatozoa may be traced. In some tubes or parts of tubes the daughter-cells may be seen to have assumed a pear shape, with the pointed end, in which the nucleus is to be found, directed toward the inner seminal cells, while the broad part is directed into the lumen of the tube. In other parts of a tube the broad end may be seen to have become elongated into a rod-shaped body, which constitutes the middle piece of the spermatozoan, while the nucleus forms the head. Again, in other parts of the tubes these young spermatozoa may be seen collected together into fan-shaped groups, and from their distal-end—that is to say, the end projecting into the lumen of the tube—a thin long filament, called the tail, is growing out. In the young subject the seminal cells present somewhat the appearance of an epithelial lining, and do not almost fill the tube, as in the adult testis.

The tubules are enclosed in a delicate plexus of capillary vessels, and are held together by an intertubular connective tissue, which presents large interstitial spaces lined by endothelium, which are believed to be the rootlets of lymphatic vessels of the testis.

In the apices of the lobules the tubuli become less convoluted, assume a nearly straight course, and unite together to form from twenty to thirty larger ducts, of about $\frac{3}{16}$ of an inch in diameter, and these, from their straight course, are called vasa recta or tubuli recti.

The vasa recta enter the fibrous tissue of the mediastinum, and pass upward and backward, forming, in their ascent, a close network of anastomosing tubes, which are merely channels in the fibrous stroma, having no proper walls; this constitutes the rete testis. At the upper end of the mediastinum the vessels of the rete testis terminate in from twelve to fifteen or twenty ducts, the vasa efferentia: they perforate the tunica albuginea, and carry the seminal fluid from the testis to the epididymis. Their course is at first straight; they then become enlarged and exceedingly convoluted, and form a series of conical masses, the coni vasculosi, which, together, constitute the globus major of the epididymis. Each cone consists of a single convoluted duct from six to eight inches in length, the diameter of which gradually decreases from the testis to the epididymis. Opposite the bases of the cones the efferent vessels open at narrow intervals into a single duct, which constitutes, by its complex convolutions, the body and globus minor of the epididymis. When the convolutions of this tube are unravelled it
measures upward of twenty feet in length, and increases in breadth and thickness as it approaches the vas deferens. The convolutions are held together by fine areolar tissue and by bands of fibrous tissue.

The vasa recta are of smaller diameter than the seminal tubes, and have very thin parietes. They, as well as the channels of the rete testis, are lined by a single layer of flattened epithelium. The vasa efferentia and the tube of the epididymis have walls of considerable thickness, on account of the presence in them of muscular tissue, which is principally arranged in a circular manner. These tubes are lined by columnar ciliated epithelium.

The Vas Deferens, the excretory duct of the testis, is the continuation of the epididymis. Commencing at the lower part of the globus minor, it ascends along the posterior border of the testis and inner side of the epididymis, and along the back part of the spermatic cord, through the spermatic canal to the internal or deep abdominal ring. From the ring it curves round the outer side of the epigastric artery, crosses the external iliac vessels, and descends into the pelvis at the side of the bladder; it arches backward and downward to its base, crossing over the obliterated hypogastric artery and to the inner side of the ureter. At the base of the bladder it lies between that viscus and the rectum, running along the inner border of the vesicula seminalis. In this situation it becomes enlarged and sacculated, forming the ampulla, and then, becoming narrowed at the base of the prostate, unites with the duct of the vesicula seminalis to form the ejaculatory duct. The vas deferens presents a hard and cord-like sensation to the fingers; it is about two feet in length, of cylindrical form, and about a line and a quarter in diameter. Its walls are dense, measuring one-third of a line, and its canal is extremely small, measuring about half a line.

Structure.—The vas deferens consists of three coats: 1. An external or cellular coat. 2. A muscular coat, which in the greater part of the tube consists of two layers of unstriped muscular fibre: an outer, longitudinal in direction, and an inner, circular; but in addition to these, at the commencement of the vas deferens, there is a third layer, consisting of longitudinal fibres, placed internal to the circular stratum, between it and the mucous membrane. 3. An internal or mucous coat, which is pale, and arranged in longitudinal folds; its epithelial covering is of the columnar variety.

A long narrow tube, the vas aberrans of Haller, is occasionally found connected with the lower part of the canal of the epididymis or with the commencement of the vas deferens. It extends up into the cord for about two or three inches, where it terminates by a blind extremity, which is occasionally bifurcated. Its length varies from an inch and a half to fourteen inches, and sometimes it becomes dilated toward its extremity; more commonly it retains the same diameter throughout. Its structure is similar to that of the vas deferens. Occasionally it is found unconnected with the epididymis. (For organ of Giraldès or paradidyemis see page 136).

Surgical Anatomy.—The testicle frequently requires removal for malignant disease; in tuberculous disease, to prevent systemic infection; in cystic disease; in cases of large hernia testis, and in some instances of incompletely descended or misplaced testicle, and for prostatic hypertrophy. The operation is a comparatively simple one. An incision is made from the external ring to the bottom of the scrotum into the tunica vaginalis. The coverings are shelled off the organ, and the mesorchium, stretching between the back of the testicle and the scrotum, divided. The cord is then isolated, and an aneurism needle, armed with a double ligature,
passed under it, as high as is thought necessary, and the cord tied in two places, and divided between the ligatures. Sometimes, in cases of malignant disease, it is desirable to open the inguinal canal and tie the cord as near the internal abdominal ring as possible.

**VESICULÆ SEMINALES.**

The **Seminal Vesicles** are two lobulated membranous pouches placed between the base of the bladder and the rectum, serving as reservoirs for the semen, and secreting a fluid to be added to the secretion of the testicles. Each sac is somewhat pyramidal in form, the broad end being directed backward and the narrow end forward toward the prostate. They measure about two and a half inches in length, about five lines in breadth, and two or three lines in thickness. They vary, however, in size, not only in different individuals, but also in the same individual on the two sides. Their **upper surface** is in contact with the base of the bladder, extending from near the termination of the ureters to the base of the prostate gland. Their **under surface** rests upon the rectum, from which they are separated by the recto-vesical fascia. Their **posterior extremities** diverge from each other. Their **anterior extremities** are pointed, and converge toward the base of the prostate gland, where each joins with the corresponding vas deferens to form the ejaculatory duct. Along the inner margin of each vesicula runs the enlarged and convoluted vas deferens. The inner border of the vesiculae and the corresponding vas deferens form the lateral boundaries of a triangular space, limited behind by the recto-vesical peritoneal fold; the portion of the bladder included in this space rests on the rectum, its antero-inferior portion corresponding with the trigonum vesicis in its interior.

Each vesicula consists of a single tube, coiled upon itself and giving off several irregular caecal diverticula, the separate coils, as well as the diverticula, being connected together by fibrous tissue. When uncoiled this tube is about the diameter of a quill, and varies in length from four to six inches; it terminates posteriorly in a **cul-de-sac**; its anterior extremity becomes constricted into a narrow straight duct, which joins on its inner side with the corresponding vas deferens, and forms the ejaculatory duct.

The **ejaculatory ducts**, two in number, one on each side, are formed by the junction of the ducts of the vesiculae seminales with the vas deferentia. Each duct is about three-quarters of an inch in length; it commences at the base of the prostate, and runs forward and downward between the middle and lateral lobes, and along the side of the sinus pectoralis, to terminate by a separate slit-like orifice close

*Fig. 741.—Base of the bladder, with the vasa deferentia and vesiculae seminales.*
to or just within the margins of the sinus (verumontanum). The ducts diminish in size and converge toward their termination.

Structure.—The vesicule seminales are composed of three coats: an external or fibro-cellular; a middle or muscular coat, which is thinner than in the vas deferens: the muscular fibres are arranged in three layers, consisting of an inner and outer longitudinal stratum and an intermediate layer of circular fibres; and an internal or mucous coat, which is pale, of a whitish-brown color, and presents a delicate reticular structure, like that seen in the gall-bladder, but the meshes are finer. The epithelium is columnar.

The coats of the ejaculatory ducts are extremely thin. They are: an outer fibrous layer, which is almost entirely lost after their entrance into the prostate; a layer of muscular fibres, consisting of an outer thin circular and an inner longitudinal layer; and the mucous membrane, forming the only constituents of the tubes.

Vessels and Nerves.—The arteries supplying the vesicule seminales are derived from the middle and inferior vesical and middle hemorrhoidal. The veins and lymphatics accompany the arteries. The nerves are derived from the pelvic plexus.

Surgical Anatomy.—The vesiculae seminales are often the seat of an extension of the disease in cases of tuberculous disease of the testicle, and should always be examined from the rectum before coming to a decision with regard to castration in this affection.

Descent of the Testes.

The testes at an early period of foetal life are placed at the back part of the abdominal cavity, behind the peritoneum, in front and a little below the kidneys. The anterior surface and sides are invested by peritoneum. At about the third month of intra-uterine life a peculiar structure, the gubernaculum testis, makes its appearance. This structure is at first a slender band which extends from the situation of the internal ring to the epididymis and body of the testicle, and is then continued upward in front of the kidney toward the Diaphragm. As development advances the peritoneum covering the testicle encloses it and forms a mesentery, the mesorchium, which also encloses the gubernaculum and forms two folds—one above the testicle, and the other below it. The one above the testicle is the plica vascularis, and contains ultimately the spermatic vessels; the one below, the plica gubernatrix, contains the lower part of the gubernaculum, which has now grown into a thick cord; it terminates below at the internal ring in a tube of peritoneum, the processus vaginalis, which now lies in the inguinal canal. The lower part of the gubernaculum by the fifth month has become a thick cord, whilst the upper part has disappeared. The lower part can now be seen to consist of a central core of unstripped muscle-fibre, and outside this of a firm layer of striped elements, connected, behind the peritoneum, with the abdominal wall. Later on, about the sixth month, the lower end of the gubernaculum can be traced into the inguinal canal, extending to the pubes, and, at a later period, to the bottom of the scrotum. The fold of peritoneum constituting the processus vaginalis projects itself downward into the inguinal canal, forming a gradually elongating depression or cul-de-sac, which eventually reaches the bottom of the scrotum. This cul-de-sac is now invaginated by the testicle, as the body of the foetus grows, for the gubernaculum does not grow commensurately with the growth of other parts, and therefore the testicle, being attached by the gubernaculum to the bottom of the scrotum, is prevented from rising as the body grows, and is drawn first into the inguinal canal, and eventually into the scrotum. By the eighth month the testicle has reached the scrotum, preceded by the lengthened pouch of peritoneum, the processus vaginalis, which communicates by its upper extremity with the peritoneal cavity. Just before birth the upper part of the pouch usually becomes closed, and this obliteration extends gradually downward to within a short distance of the testis. The process of peritoneum surrounding the testis, which is
now entirely cut off from the general peritoneal cavity, constitutes the \textit{tunica vaginalis}.\footnote{The obliteration of the process of peritoneum which accompanies the cord, and is hence called the \textit{funicular process}, is often incomplete. See section on Inguinal Hernia.}

In the female, a small cord, corresponding to the gubernaculum in the male, descends to the inguinal region, and ultimately forms the round ligament of the uterus. A pouch of peritoneum accompanies it along the inguinal canal, analogous to the processus vaginalis in the male: it is called the \textit{canal of Nuck}.

\textbf{Surgical Anatomy.---}Abnormalities in the formation and in the descent of the testicle may occur. The testicle may fail to be developed, or the testicle may be fully developed and the vas deferens may be undeveloped in whole or part; or, again, both testicle and vas deferens may be fully developed, but the duct may not become connected to the gland. The testicle may fail in its descent (\textit{cryptorchismus}), or it may descend into some abnormal position. Thus it may be retained in the position where it was primarily developed, below the kidney; or it may descend to the internal abdominal ring, but fail to pass through this opening; it may be retained in the inguinal canal, which is perhaps the most common position; or it may pass through the external abdominal ring and remain just outside it, failing to pass to the bottom of the scrotum. On the other hand, it may get into some abnormal position: it may pass the scrotum and reach the perineum, or it may fail to enter the inguinal canal, and may find its way through the femoral ring into the crural canal, and present itself on the thigh at the saphenous opening. There is still a third class of cases of abnormality of the testicle, where the organ has descended in due course into the scrotum, but is misplaced. The most common form of this is where the testicle is \textit{inverted}; that is to say, the organ is rotated, so that the epididymis is connected to the front of the scrotum, and the body, surrounded by the tunica vaginalis, is directed backward. In these cases the vas deferens is to be felt in the front of the cord. The condition is of importance in connection with hydrocele and haematoccele, and the position of the testicle should always be carefully ascertained before performing any operation for these affections. Again, more rarely, the testicle may be \textit{reversed}. This is a condition in which the top of the testicle, indicated by the globus major of the epididymis, is at the bottom of the scrotum, and the vas deferens comes off from the summit of the organ.
THE FEMALE GENERATIVE ORGANS.

EXTERNAL ORGANS.

The External Organs of Generation in the Female are: the mons Veneris, the labia majora and minora, the clitoris, the meatus urinarius, and the orifice of the vagina. The term "vulva" or "pudendum," as generally applied, includes all these parts.

The Mons Veneris is the rounded eminence in front of the pubic symphysis, formed by a collection of fatty tissue beneath the integument. It surmounts the vulva, and becomes covered with hair at the time of puberty.

The Labia Majora are two prominent longitudinal cutaneous folds extending downward from the mons Veneris to the anterior boundary of the perineum, and
enclosing the common urino-sexual opening. Each labium is formed of two folds of integument: covered with hair externally; internally, smooth and pinkish. The inner fold is continuous with the genito-urinary mucous tract. Between the two folds is a quantity of areolar tissue, fat, and a tissue resembling the dartos of the scrotum, besides vessels, nerves, and glands. The labia are thicker in front, where they form by their meeting the anterior commissure. Posteriorly they are not really joined, but appear to become lost in the neighboring integument, terminating close to, and nearly parallel with, each other. Together with the connecting skin between them, they form the posterior commissure or posterior boundary of the vulval orifice. The interval between the posterior commissure and

![Diagram of female pelvis](image)

Fig. 743.—Vertical median section of the female pelvis.

the anus, about an inch to an inch and a quarter in length, constitutes the perineum or base of the perineal body. The fourchette is the anterior edge of the latter, and between it and the hymen is a depression, the fossa navicularis. The labia correspond to the scrotum in the male.

The Labia Minora, or Nymphae, are two small cutaneous folds, situated within the labia majora, and extending from the clitoris obliquely downward, outward, and backward for about an inch and a half on each side of the orifice of the vagina, between which and the labia majora they are lost. Anteriorly, the two labia minora meet and form the frenum of the clitoris. The prepuce of the clitoris, passing backward on each side, is inserted, as it were, into each labium minus. The nymphae are really modified skin. Their internal surfaces have numerous sebaceous follicles.

The Clitoris is an erectile structure analogous to the corpora cavernosa of the penis. It is situated beneath the anterior commissure, partially hidden between the anterior extremities of the labia minora. It is connected to the rami of the os pubis
and ischium on each side by a crus; the body is short and concealed beneath the labia; the free extremity, or glans clitoridis, is a small rounded tubercle, consisting of spongy erectile tissue, and highly sensitive. It is provided, like the penis, with a suspensory ligament, and with two small muscles, the Erectores clitoridis, which are inserted into the crura of the clitoris. The clitoris consists of two corpora cavernosa, composed of erectile tissue enclosed in a dense layer of fibrous membrane, united together along their inner surfaces by an incomplete fibrous pectiniform septum.

Between the clitoris and the entrance of the vagina is a triangular smooth surface, bounded on each side by the nymphae: this is the vestibule.

The orifice of the urethra (meatus urinarius) is situated at the back part of the vestibule, about an inch below the clitoris and near the margin of the vagina, surrounded by a prominent elevation of the mucous membrane. Below the meatus urinarius is the orifice of the vagina, more or less closed in the virgin by a membranous fold, the hymen.

The Hymen is a membranous fold which closes to a greater or less extent the opening of the vagina. It varies much in shape. Its commonest form is that of a ring, generally broadest posteriorly: sometimes it is represented by a semilunar fold, with its concave margin turned toward the pubes. A complete septum stretched across the lower part of the vaginal orifice is called "imperforate hymen." Occasionally it is cribriform, or its free margin forms a membranous fringe, or it may be entirely absent. It may persist after copulation, so that it cannot be considered as a test of virginity. After parturition the small rounded elevations known as the carunculae myrtiformes are found as the remains of the hymen.

Glands of Bartholin.—On each side of the commencement of the vagina, and

![Diagram of female reproductive organs]{fig:744.—Longitudinal section through the pelvis of a young woman. (Bardeleben.)}
behind the hymen, is a round or oblong body, of a reddish-yellow color, and of the size of a horse-bean, analogous to Cowper’s gland in the male. It is called the gland of Bartholin. Each gland opens by means of a long single duct on each side external to the hymen.

**RELATIONS OF THE BLADDER.**

The Bladder is situated at the anterior part of the pelvis. It is in relation, in front, with the symphysis pubis; behind, with the utero-vesical pouch of peritoneum, which separates it from the body of the uterus; its base lies in contact with the connective tissue in front of the cervix and upper part of the vagina. Laterally, is the recto-vesical fascia. The bladder is said by some anatomists to be larger in

---

**Bulbi Vestibuli.**—Extending from the clitoris, along either side of the vestibule, and lying a little behind the nymphæ, are two large oblong masses, about an inch in length, consisting of a plexus of veins enclosed in a thin layer of fibrous membrane. These bodies are narrow in front, rounded below, and are connected with the crura of the clitoris and rami of the pubes: they are termed by Kobelt the bulbi vestibuli, and he considers them analogous to the bulb of the corpus spongiosum in the male. Immediately in front of these bodies is a smaller venous plexus, continuous with the bulbi vestibuli behind and the glans clitoridis in front: it is called by Kobelt the pars intermedia, and is considered by him as analogous to that part of the body of the corpus spongiosum which immediately succeeds the bulb.
the female than in the male. At any rate, it does not rise above the symphysis pubis till more distended than in the male, but this is perhaps owing to the more capacious pelvis rather than to its being of actually larger size.

THE URETHRA.

The Urethra is a narrow membranous canal, about an inch and a half in length, extending from the neck of the bladder to the meatus urinarius. It is placed beneath the symphysis pubis, imbedded in the anterior wall of the vagina; and its direction is obliquely downward and forward, its course being slightly curved. The concavity directed forward and upward. Its diameter when undilated is about a quarter of an inch. The urethra perforates the triangular ligament precisely as in the male.

Structure.—The urethra consists of three coats: muscular, erectile, and mucous.

The muscular coat is continuous with that of the bladder; it extends the whole length of the tube, and consists of a circular stratum of muscular fibres. In addition to this, between the two layers of the triangular ligament, the female urethra is surrounded by the Compressor urethrae, as in the male.

A thin layer of spongy erectile tissue, containing a plexus of large veins intermixed with bundles of unstriped muscular fibre, lies immediately beneath the mucous coat.

The mucous coat is pale, continuous externally with that of the vulva, and internally with that of the bladder near which it contains many tubular mucous glands. It is thrown into longitudinal folds, one of which placed along the floor of the canal, resembles the verumontanum in the male urethra. It is lined by laminated epithelium, which becomes transitional near the bladder. Its external orifice is surrounded by a few mucous follicles.

The urethra, from not being surrounded by dense resisting structures, as in the male, admits of considerable dilatation, which enables the surgeon to remove with considerable facility calculi or other foreign bodies from the cavity of the bladder.

THE RECTUM.

The Rectum is more capacious and less curved in the female than in the male.

The first portion extends from the left sacro-iliac articulation to the middle of the sacrum. Its connections are similar to those in the male.

The second portion extends to the tip of the coccyx. It is covered in front by the peritoneum for a short distance, at its upper part; it is in relation with the posterior wall of the vagina.

The third portion curves backward from the vagina to the anus, leaving a space which corresponds on the surface of the body to the perineum. Its extremity is surrounded by the Sphincter muscles, and its sides are supported by the Levatores ani.

INTERNAL ORGANS.

The Internal Organs of Generation are—the vagina, the uterus and its appendages, the Fallopian tubes, the ovaries and their ligaments, and the round ligaments.

The Vagina extends from the vulva to the uterus. It is situated in the cavity of the pelvis, behind the bladder and in front of the rectum. Its direction is curved upward and backward, at first in the line of the outlet, and afterward in that of the axis of the cavity of the pelvis. Its walls are ordinarily in contact, and its usual shape on transverse section is that of an H, the transverse limb being slightly curved forward or backward, whilst the lateral limbs are somewhat convex toward the median line. Its length is about two and a half inches along its anterior wall, and three and a half inches along its posterior wall. It is constricted at its commencement, and becomes dilated medially, and narrowed near its uterine extremity; it surrounds the vaginal portion of the cervix uteri, a short
distance from the os, its attachment extending higher up on the posterior than on the anterior wall of the uterus.

**Relations.**—Its anterior surface is in relation with the base of the bladder and with the urethra. Its posterior surface is connected for the lower three-fourths of its extent to the anterior wall of the rectum, the upper fourth being separated from that tube by the recto-vaginal fold of peritoneum, which forms a cul-de-sac between the vagina and rectum. Its sides give attachment superiorly to the broad ligaments, and inferiorly to the Levatores ani muscles and recto-vesical fascia.

**Structure.**—The vagina consists of an internal mucous lining, of a muscular coat, and between the two of a layer of erectile tissue.

The mucous membrane is continuous above with that lining the uterus. Its inner surface presents, along the anterior and posterior walls, a longitudinal ridge or raphe, called the columns of the vagina, and numerous transverse ridges or rugae, extending outward from the raphe on either side. These rugae are divided by furrows of variable depth, giving to the mucous membrane the appearance of being studded over with conical projections. There are also microscopic papillae; the projections are most numerous near the orifice of the vagina, especially in females before parturition. The epithelium covering the mucous membrane is of the squamous variety. The submucous tissue is very loose and contains numerous large veins, which by their anastomoses form a plexus, together with smooth muscular fibres derived from the muscular coat; it is regarded by Gussenbauer as an erectile tissue. It contains a number of mucous crypts, but no true glands.

The muscular coat consists of two layers: an external longitudinal, which is far the stronger, and an internal circular layer. The longitudinal fibres are continuous with the superficial muscular fibres of the uterus. The strongest fasciculi are those attached to the recto-vesical fascia on each side. The two layers are not distinctly separable from each other, but are connected by oblique decussating fasciculi which pass from the one layer to the other. In addition to this the vagina at its lower end is surrounded by a band of striped muscular fibres, the sphincter vaginae (see page 464).

External to the muscular coat is a layer of connective tissue containing a large plexus of blood-vessels.

The erectile tissue consists of a layer of loose connective tissue situated between the mucous membrane and the muscular coat; imbedded in it is a plexus of large veins, and numerous bundles of unstriped muscular fibres derived from the circular muscular layer. The arrangement of the veins is similar to that found in other erectile tissues.

**THE UTERUS.**

The Uterus is the organ of gestation, receiving the fecundated ovum in its cavity, retaining and supporting it during the development of the fetus, and becoming the principal agent in its expulsion at the time of parturition.

In the virgin state it is pear-shaped, flattened from before backward, and situated in the cavity of the pelvis between the bladder and the rectum; it is retained in its position by the round and broad ligaments on each side, and projects into the upper end of the vagina below. Its upper end, or base, is directed upward and forward; its lower end, or apex, downward and backward, in the line of the axis of the inlet of the pelvis. It therefore forms an angle with the vagina, since the direction of the vagina corresponds to the axis of the cavity and outlet of the pelvis. The uterus measures about three inches in length, two in breadth at its upper part, and nearly an inch in thickness, and it weighs from an ounce to an ounce and a half.

It consists of two parts: (1) the body, with its upper broad extremity, the fundus; and (2) the cervix, or neck, which is partly above the vagina and partly in the vagina. The fundus is placed on a line below the level of the brim of the pelvis, being directed forward behind the upper portion of the anterior pelvic wall.
The division between the body and cervix is indicated externally by a slight constriction, and by the reflection of the peritoneum from the anterior surface of the uterus on to the bladder, and internally by a narrowing of the canal, called the internal os.

The body gradually narrows from the fundus to the neck. Its anterior surface is flattened, compared to the posterior, covered by peritoneum throughout, and separated from the bladder by the utero-vesical pouch. Its posterior surface is convex transversely, covered by peritoneum throughout, and separated from the rectum by some convolutions of the intestine. Its lateral margins are concave, and give attachment to the Fallopian tube above, the round ligament below and in front of this, and the ligament of the ovary behind both of these structures.

The cervix is the lower constricted segment of the uterus; around its circumference is attached the upper end of the vagina, which extends upward a greater distance behind than in front.

The supravaginal portion is not covered by peritoneum in front; a pad of cellular tissue is interposed between it and the bladder. Behind, the peritoneum is extended over its upper part. The vaginal portion is the rounded lower end projecting into the vagina. On its surface is a small aperture, the os uteri, generally circular in shape, but sometimes oval or almost linear. The margin of the opening is, in the absence of past parturition or disease, quite smooth.

Ligaments.—The ligaments of the uterus are eight in number: one anterior; one posterior; two lateral or broad; two sacro-uterine,—all these being formed of peritoneum—and, lastly, two round ligaments.

The anterior ligament (vesico-uterine) is reflected on to the bladder from the front of the uterus, at the junction of the supravaginal cervix and body.

The posterior ligament (recto-uterine) passes from the posterior wall of the uterus over the upper fourth of the vagina, and thence on to the rectum and sacrum. It thus forms a pouch called Douglas's pouch (Fig. 747), the boundaries of which are, in front, the posterior wall of the uterus, the supravaginal cervix, and the upper
fourth of the vagina; behind, the rectum and sacrum; above, the small intestine; and, laterally, the sacro-uterine ligaments investing recto-vesical fascia.

The two lateral or broad ligaments pass from the sides of the uterus to the lateral walls of the pelvis, forming a septum across the pelvis, which divides that cavity into two portions. In the anterior part are contained the bladder, urethra, and vagina; in the posterior part, the rectum. Between the two layers of each broad ligament are contained—(1) the Fallopian tubes superiorly; (2) the round ligament; (3) the ovary and its ligament; (4) the parovarium, or organ of Rosenmüller; (5) connective tissue; and (6) unstriped muscular fibre. Between the fimbriated extremity of the tube and the lower attachment of the broad ligament is a concave rounded margin called the infundibulo-pelvic ligament (Fig. 752). The upper border is often known as the mesosalpinx.

The sacro-uterine ligaments pass from the second and third bones of the sacrum, downward and forward, to be attached one on each side of the uterus at the junction of the supravaginal cervix and the body, this point corresponding internally to the position of the os internum. (For the round ligaments, see page 1177.)

The cavity of the uterus is small in comparison with the size of the organ; that portion of the cavity which corresponds to the body is triangular, flattened from before backward, so that its walls are closely approximated, and having its base directed upward toward the fundus. At each superior angle is a funnel-shaped cavity, which constitutes the remains of the division of the body of the uterus into two cornua, and at the bottom of each cavity is the minute orifice of the Fallopian tube. At the inferior angle of the uterine cavity is a small constricted opening, the internal orifice (ostium internum), which leads into the cavity of the cervix.
The cavity of the cervix is somewhat fusiform, flattened from before backward, broader at the middle than at either extremity, and communicates below with the vagina. The wall of the canal presents, anteriorly and posteriorly, a longitudinal column, from which proceed a number of small oblique columns, giving the appearance of branches from the stem of a tree; and hence the name arbor vitæ uterina applied to it. These folds usually become very indistinct after the first labor (Fig. 750).

Structure.—The uterus is composed of three coats—an external serous coat, a middle or muscular, and an internal mucous coat.
The serous coat is derived from the peritoneum; it invests the fundus and the whole of the posterior surface of the body of the uterus, but only the upper three-fourths of its anterior surface. In the lower fourth of the posterior surface the peritoneum, though covering the uterus, is not closely connected with it, being separated from it by a layer of loose cellular tissue and some large veins.

The muscular coat forms the chief bulk of the substance of the uterus. In the unimpregnated state it is dense, firm, of a grayish color, and cuts almost like cartilage. It is thick opposite the middle of the body and fundus, and thin at the orifices of the Fallopian tubes. It consists of bundles of unstripped muscular fibres, disposed in layers, intermixed with areolar tissue, blood-vessels, lymphatic vessels, and nerves. In the impregnated state the muscular tissue becomes more prominently developed, and is disposed in three layers—external, middle, and internal.

The external layer is placed beneath the peritoneum, disposed as a thin plane on the anterior and posterior surfaces. It consists of fibres which pass transversely across the fundus, and, converging at each superior angle of the uterus, are continued on the Fallopian tube, the round ligament, the ligament of the ovary: some passing at each side into the broad ligament, and others running backward from the cervix into the sacro-uterine ligaments.

The middle layer of fibres, which is thickest, presents no regularity in its arrangement, being disposed longitudinally, obliquely, and transversely. It contains most blood-vessels.

The internal or deep layer is the greatly hypertrophied muscularis mucosae of the mucous membrane. It consists of circular fibres arranged in the form of two hollow cones, the apices of which surround the orifices of the Fallopian tubes, their bases intermingling with one another on the middle of the body of the uterus. At the internal os these circular fibres form a distinct sphincter.

The mucous membrane is smooth, and closely adherent to the subjacent tissue. It is continuous, through the fimbriated extremity of the Fallopian tubes, with the peritoneum, and through the os uteri with the lining of the vagina.

In the body of the uterus it is smooth, soft, of a pale red color lined by columnar ciliated epithelium, and presents, when viewed with a lens, the orifices of numerous tubular follicles arranged perpendicularly to the surface. It is provided with any submucosa, but is intimately connected with the innermost layer of the muscular coat, which is regarded as the muscularis mucosae. In structure its corium differs from ordinary mucous membrane, consisting of an embryonic nucleated and highly cellular form of connective tissue in which run numerous large lymphatics. In it are the tube-like uterine glands, which are of small size in the unimpregnated uterus, but shortly after impregnation become enlarged, elongated, presenting a contorted or waved appearance toward their closed extremities, which reaches into the muscularis, and may be single or bifid. They consist of a delicate membrane, lined by an epithelium, which becomes ciliated toward the orifices. In the impregnated uterus the epithelium loses its ciliated character, is thicker and tougher, and is provided with a submucous layer of areolar tissue.

In the cervix the mucous membrane is sharply differentiated from that of the uterine cavity. It is thrown into numerous transverse folds, which are arranged along an anterior and posterior longitudinal raphe, presenting an appearance which has received the name of arbor vitae. In the upper two-thirds of the canal the mucous membrane is provided with numerous deep glandular follicles, which secrete a clear viscid alkaline mucus; and in addition, extending through the whole length of the canal, are a variable number of little cysts, presumably follicles, which have become occluded and distended with retained secretion. They are called the ovula Nabothi. The mucous membrane covering the lower half of the cervical canal presents numerous papillae. The epithelium of the upper two-thirds is columnar and ciliated, but below this it loses its cilia, and gradually changes to squamous epithelium close to the external os.
Vessels and Nerves.—The arteries of the uterus are the uterine, from the internal iliac, and the ovarian, from the aorta. They are remarkable for their tortuous course in the substance of the organ and for their frequent anastomoses. The termination of the ovarian artery meets the termination of the uterine artery, and forms an anastomotic trunk from which branches are given off to supply the uterus, their disposition being, as shown by John Williams, circular. The veins are of large size, and correspond with the arteries. In the impregnated uterus these vessels are termed the uterine sinuses, consisting of the lining membrane of the veins adhering to the walls of the canal channelled through the substance of the uterus. They terminate in the uterine plexuses. The lymphatics of the body terminate in the lumbar glands, those of the cervix in the pelvic glands. The nerves are derived from the inferior hypogastric and ovarian plexuses, and from the third and fourth sacral nerves.

The form, size, and situation of the uterus vary at different periods of life and under different circumstances.

In the fetus the uterus is contained in the abdominal cavity, projecting beyond the brim of the pelvis. The cervix is considerably larger than the body.

At puberty the uterus is pyriform in shape, and weighs from eight to ten drachms. It has descended into the pelvis, the fundus being just below the level of the brim of this cavity. The arbor vitae is distinct, and extends to the upper part of the cavity of the organ.

During menstruation the organ is enlarged, and more vascular, its surfaces rounder; the os externum is rounded, its labia swollen, and the lining membrane of the body thickened, softer and of a darker color. According to J. Williams, at each recurrence of menstruation a molecular disintegration of the mucous membrane takes place, which leads to its complete removal, only the bases of the glands imbedded in the muscle being left. At the cessation of menstruation by a proliferation of the remaining structures a fresh mucous membrane is formed.

During pregnancy the uterus becomes enormously enlarged, and in the ninth month reaches the epigastric region. The increase in size is partly due to growth of pre-existing muscle and partly to development of new fibres.

After parturition the uterus nearly regains its usual size, weighing about an ounce and a half; but its cavity is larger than in the virgin state. the external orifice is more marked, its edges present a fissured surface, its vessels are tortuous, and its muscular layers are more defined.
In old age the uterus becomes atrophied, and paler and denser in texture; a more distinct constriction separates the body and cervix. The ostium internum and, occasionally, the vaginal orifice often become obliterated, and its labia almost entirely disappear.

APPENDAGES OF THE UTERUS.

The appendages of the uterus are the Fallopian tubes, the ovaries and their ligaments, and the round ligaments. They are placed in the following order: in front is the round ligament; the Fallopian tube occupies the upper margin of the broad ligament; the ovary and its ligament are behind and below both.

THE FALLOPIAN TUBES.

The Fallopian Tubes, or Oviducts, convey the ova from the ovaries to the cavity of the uterus. They are two in number, one on each side, situated in the upper margin of the broad ligament, extending from each superior angle of the uterus to the sides of the pelvis. Each tube is about four inches in length; and is described as consisting of three portions: (1) the isthmus, or inner constricted half; (2) the ampulla, or outer dilated portion, which curves over the ovary; and (3) the infundibulum with its ostium abdominale, surrounded by fimбриe, one of which is attached to the ovary, the fimbra ovarica. The general direction of the Fallopian tube is outward and upward, backward and downward. The uterine opening is minute, and will only admit a fine bristle; the abdominal opening is comparatively much larger. In connection with the fimбриe of the Fallopian tube or with the broad ligament close to them there is frequently one or more small vesicles floating on a long stalk of peritoneum. These are termed the hydatids of Morgagni, and are probably of peritoneal origin.

Structure.—The Fallopian tube consists of three coats—serous, muscular, and mucous.

The external or serous coat is peritoneal.

The middle or muscular coat consists of an external longitudinal and an internal circular layer of muscular fibres continuous with those of the uterus.

The internal or mucous coat is continuous with the mucous lining of the uterus and, at the free extremity of the tube, with the peritoneum. It is thrown into longitudinal folds, which in the outer, larger part of the tube, or ampulla, are much more extensive than in the narrow canal of the isthmus. The lining epithelium is columnar ciliated. This form of epithelium is also found on the inner surface of the fimбриe, while on the outer or serous surfaces of these processes the epithelium gradually merges into the endothelium of the peritoneum.
THE OVARIES.

The **Ovaries** (*testes muliebres*, Galen) are analogous to the testes in the male. They are oval-shaped, flattened bodies of an elongated form, situated one on each side of the uterus, connected to the posterior layer of the broad ligament behind and below the Fallopian tubes. Each ovary is connected by its anterior straight margin to the broad ligaments; by its lower extremity to the uterus by a proper ligament, the *ligament of the ovary*; and by its upper end to the fimbriated extremity of the Fallopian tube by the ovarian fimbria; its mesial and lateral surfaces and posterior convex border are free. The ovaries are of a grayish-pink color, and present either a smooth or puckered, uneven surface. They are each about an inch and a half in length, three-quarters of an inch in width, and about a third of an inch thick, and weight from one to two drachms.

The exact position of the ovary has been the subject of considerable difference of opinion, and writers differ much as to what is to be regarded as the normal position. The fact appears to be that it is differently placed in different individuals. Hasse has described it as being situated with its long axis transverse, or almost transverse, to the pelvic cavity. Schultze, on the other hand, believes that its long axis is antero-posterior. Kölliker asserts that the truth lies between these two views, and that the ovary is placed obliquely in the pelvis, its long axis lying parallel to the external iliac vessels, with its surface directed inward and outward, and its convex free border upward. His has made some important observations on this subject, and his views are largely accepted. He teaches that the uterus rarely lies symmetrically in the middle of the pelvic cavity, but is generally inclined to one or other side, most frequently to the left, in the proportion of three to two. The position of the two ovaries varies according to the inclination of the uterus. When the uterus is inclined to the left, the ovary of this side lies with its long axis vertical and with one side closely applied to the outer wall of the pelvis, while the ovary of the opposite side, being dragged upon by the inclination of the uterus, lies obliquely, its outer extremity being retained in close apposition to the side of the pelvis by the infundibulopelvic ligament (page 1170). When, on the other hand, the uterus is inclined to the right, the position of the two ovaries is exactly reversed, the right being vertical and the left oblique. In whichever position the ovary is placed, the Fallopian tube forms a loop around it, the uterine half ascending obliquely over it, and the outer half, including the dilated extremity, descending and bulging freely behind it. From this extremity the fimbria pass upward on to the ovary and closely embrace it.

**Structure.**—The ovary consists of a number of Graafian vesicles imbedded in

---

**Fig. 753.**—The uterus and its appendages. Posterior view. The parts have been somewhat displaced from their proper position in the preparation of the specimen; thus the right ovary has been raised above the Fallopian tube, and the fimbriated extremities of the tubes have been turned upward and outward. (From a preparation in the Royal College of Surgeons.)
the meshes of a stroma or framework, and invested by a serous covering derived from the peritoneum.

_Serous Covering._—Though the investing membrane of the ovary is derived from the peritoneum, it differs essentially from that structure, inasmuch as its epithelium consists of a single layer of columnar cells, instead of the flattened endothelial cells of other parts of the membrane; this has been termed the _germinial epithelium of Waldeyer_, and gives to the surface of the ovary a dull gray aspect instead of the shining smoothness of serous membranes generally.

_Stroma._—The stroma is a peculiar soft tissue, abundantly supplied with blood-vessels, consisting for the most part of spindle-shaped cells, with a small amount of ordinary connective tissue. These cells have been regarded by some anatomists as unstriped muscle-cells, which, indeed, they most resemble (His); by others as connective-tissue cells (Waldeyer, Henle, and Köllicker). On the surface of the organ this tissue is much condensed, and forms a layer composed of short connective-tissue fibres, with fusiform cells between them. This was formerly regarded as a distinct fibrous covering, and was termed the _tunica albuginea_, but is nothing more than a condensed layer of the stroma of the ovary.

_Graafian Follicles._—Upon making a section of an ovary numerous round transparent vesicles of various sizes are to be seen; they are the _Graafian vesicles or follicles_, the ovisacs containing the ova. Immediately beneath the superficial covering is a layer of stroma, in which are a large number of minute vesicles of uniform size, about \( \frac{3}{16} \) of an inch in diameter. These are the Graafian vesicles in their earliest condition, and the layer where they are found has been termed the _cortical layer_. They are especially numerous in the ovary of the young child. After puberty and during the whole of the child-bearing period large and mature, or almost mature, Graafian vesicles are also found in the cortical layer in small numbers, and also "corpora lutea," the remains of vesicles which have burst and are undergoing atrophy and absorption. Beneath this superficial stratum other large and more mature Graafian vesicles are found imbedded in the ovarian stroma. These increase in size as they recede from the surface toward a highly vascular stroma in the centre of the organ, termed the _medullary substance_ (zona vasculosa, Waldeyer). This stroma forms the tissue of the hilum by which the ovary is attached, and through which the blood-vessels enter; it does not contain any Graafian vesicles.

The larger _Graafian follicles_ consist of an external fibro-vascular coat connected with the surrounding stroma of the ovary by a network of blood-vessels; and an internal coat, named _ovicapsule_, which is lined by a layer of nucleated cells, called the _membrana granulosa_. The fluid contained in the interior of the vesicles is transparent and albuminous, and in it is suspended the ovum. In that part of the mature Graafian vesicle which is nearest the surface of the ovary the cells of the membrana granulosa are collected into a mass which projects into the cavity.
of the vesicle. This is termed the *discus proligerus*, and in this the ovum is imbedded.¹

The ova are formed from the germ-epithelium on the surface of the ovary: the cells become enlarged and involuted, forming little depressions on the surface of the ovary. As they sink deeper into the tissue they become enclosed by the outgrowth of processes from the stroma of the ovary, and, becoming surrounded, their connection with the surface is cut off, and the germ-epithelium forming the involution is contained in a cavity, the future Graafian follicle. The germ-cell or cells now form the ovum; the cell-wall forms the vitelline membrane; the nucleus, the germinal area or vesicle; and a nucleolus, which soon appears, the germinal spot. A clear homogeneous protoplasm is formed within the cell, constituting the yolk, and thus the primordial ovum is developed. According to Dr. Fouillis, the cells of the membrana granulosa are formed out of the nuclei of the fibro-cellular stroma of the ovary.²

The development and maturation of the Graafian vesicles and ova continue uninterruptedly from puberty to the end of the fruitful period of woman's life, while their formation commences before birth. Before puberty the ovaries are small, the Graafian vessels contained in them are disposed in a comparatively thick layer in the cortical substance; here they present the appearance of a large number of minute closed vesicles, constituting the early condition of the Graafian vesicle; many, however, never attain full development, but shrink and disappear, their ova being incapable of impregnation. At puberty the ovaries enlarge, are more vascular, the Graafian vesicles are developed in greater abundance, and their ova are capable of fecundation.

Discharge of the Ovum.—The Graafian vesicles, after gradually approaching the surface of the ovary, burst: the ovum and fluid contents are liberated, and escape on the exterior of the ovary, passing thence into the Fallopian tube.³

In the foetus the ovaries are situated, like the testes, in the lumbar region, near the kidneys. They may be distinguished from those bodies at an early period by their elongated and flattened form, and by their position, which is at first oblique and then nearly transverse. They gradually descend into the pelvis.

Lying above the ovary in the broad ligament between it and the Fallopian tube is the *organ of Rosenmüller*, called also the *parovarium*. This is the remnant of a foetal structure, described at page 137. In the adult it consists of a few closed convoluted tubes lined with epithelium, which converge toward the ovary, but which are connected at their opposite extremities with a longitudinal tube, the duct of Gartner (*epididymon*), which ends in a bulbous or hydatized swelling. The parovarium is connected at its uterine extremity with the remains of the Wolffian duct. The *paröophoron* corresponds to the paradidymis of the male, and is found, when present, near the uterus.

The Ligament of the Ovary is a rounded cord which extends from each superior angle of the uterus to the lower extremity of the ovary; it consists of fibrous tissue and a few muscular fibres derived from the uterus.

The Round Ligaments are two rounded cords, between four and five inches in length, situated between the layers of the broad ligament in front of and below the Fallopian tube. Commencing on each side at the superior angle of the uterus, this ligament passes forward, upward, and outward through the internal abdominal ring, along the inguinal canal, to the labia majora, in which it becomes lost. The round ligament consists principally of muscular tissue prolonged from the uterus: also of some fibrous and areolar tissue, besides blood-vessels and nerves, enclosed in a duplication of peritoneum, which in the foetus is prolonged in the form of a tubular process for a short distance into the inguinal canal. This process is called the *canal of Nuck*. It is generally obliterated in the adult, but sometimes remains

¹ For a description of the ovum, see page 100.
² *Proceedings of the Royal Society of Edinburgh*, April, 1873.
³ This is effected either by application of the tube to the ovary, or by a curling upward of the fimbriated extremity, so that the ovum is caught as it falls.
 pervious even in advanced life. It is analogous to the peritoneal pouch which accompanies the descent of the testis.

**Vessels and Nerves.**—The arteries of the ovaries and Fallopian tubes are the ovarian from the aorta. They enter the attached border, or hilum, of the ovary. The veins follow the course of the arteries; they form a plexus near the ovary, the *pampiniform plexus*. The nerves are derived from the inferior hypogastric or pelvic plexus, and from the ovarian plexus, the Fallopian tube receiving a branch from one of the uterine nerves.

**THE MAMMARY GLANDS.**

The *mammæ*, or breasts, are accessory glands of the generative system, which secrete the milk. They exist in the male as well as in the female, but in the former only in the rudimentary state, unless their growth is excited by peculiar circumstances. In the female they are two large hemispherical eminences situated toward the lateral aspect of the pectoral region, corresponding to the intervals between the third and sixth or seventh ribs, and extending from the side of the sternum to the axilla. Their weight and dimensions differ at different periods of life and in different individuals. Before puberty they are of small size, but enlarge as the generative organs become more completely developed. They increase during pregnancy, and especially after delivery, and become atrophied in old age. The left mamma is generally a little larger than the right. Their base is nearly circular, flattened or slightly concave, and has its long diameter directed upward and outward toward the axilla; they are separated from the Pectoral and Serratus magnus muscles by a layer of fascia. The outer surface of the mamma is convex, and presents, just below the centre, a small conical prominence, the nipple (*mammilla*). The surface of the nipple is dark-colored and surrounded by an areola having a colored tint. In the virgin the areola is of a delicate rosy hue; about the second month after impregnation it enlarges and acquires a darker tinge, which increases as pregnancy advances, becoming in some cases of a dark-brown or even black color. This color diminishes as soon as lactation is over, but is never entirely lost throughout life. These changes in the color of the areola are of importance in forming a conclusion in a case of suspected first pregnancy.

---

**Fig. 756.—Dissection of the lower half of the female breast during the period of lactation.** (From Luschka.)
The **nipple** is a cylindrical or conical eminence capable of undergoing a sort of erection from mechanical excitement, a change mainly due to the contraction of its muscular fibres. It is of a pink or brownish hue, its surface wrinkled and provided with papillæ, and it is perforated at the tip by numerous orifices, the apertures of the lactiferous ducts. Near the base of the nipple and upon the surface of the areolæ are numerous sebaceous glands, which become much enlarged during lactation, and present the appearance of small tubercles beneath the skin. These glands secrete a peculiar fatty substance, which serves as a protection to the integument of the nipple during the act of sucking. The nipple consists of numerous vessels, intermixed with plain muscular fibres, which are principally arranged in a circular manner around the base, some few fibres radiating from base to apex.

**Structure.**—The mamma consists of gland-tissue; of fibrous tissue, connecting its lobes; and of fatty tissue in the intervals between the lobes. The gland-tissue, when freed from fibrous tissue and fat, is of a pale reddish color, firm in texture, circular in form, flattened from before backward, thicker in the centre than at the circumference, and presenting several inequalities on its surface, especially in front. It consists of numerous lobes, and these are composed of lobules connected together by areolar tissue, blood-vessels, and ducts. The smallest lobules consist of a cluster of rounded alveoli, which open into the smallest branches of the lactiferous ducts; these ducts, uniting, form larger ducts, which terminate in a single canal, corresponding with one of the chief subdivisions of the gland. The number of excretory ducts varies from fifteen to twenty: they are termed the *tubuli lactiferi*, or *galactophori*. They converge toward the areola, beneath which they form dilatations, or *ampullae*, which serve as reservoirs for the milk, and at the base of the nipple become contracted and pursue a straight course to its summit, perforating it by separate orifices considerably narrower than the ducts themselves. The ducts are composed of areolar tissue, with longitudinal and transverse elastic fibres and longitudinal muscular fibres: their mucous lining is continuous, at the point of the nipple, with the integument. The epithelium of the mammary gland differs according to the state of activity of the organ. In the gland of a woman who is not pregnant or suckling the alveoli are very small and solid, being filled with a mass of granular polyhedral cells. During pregnancy the alveoli enlarge and the cells undergo rapid multiplication. At the commencement of lactation the cells in the centre of the alveolus undergo fatty degeneration, and are eliminated in the first milk as *colostrum-corpuscles*. The peripheral cells of the alveolus remain, and form a single layer of granular, short columnar cells, with a spherical nucleus, lining the limiting membrana propria. These cells during the state of activity of the gland are capable of forming, in their interior, oil-globules, which are then ejected into the lumen of the alveolus and constitute the milk-globules.

The **fibrous tissue** invests the entire surface of the breast, and sends down septa between its lobes, connecting them together.

The **fatty tissue** surrounds the surface of the gland and occupies the interval between its lobes. It usually exists in considerable abundance, and determines the form and size of the gland. There is no fat immediately beneath the areola and nipple. (The colostrum-corpuscles may be emigrated white corpuscles.)

**Vessels and Nerves.**—The *arteries* supplying the mammary are derived from the thoracic branches of the axillary, the intercostals, and internal mammary. The *veins* describe an anastomotic circle round the base of the nipple, called by Haller the *circulus venosus*. From this large branches transmit the blood to the circumference of the gland and end in the axillary and internal mammary veins. The *lymphatics*, for the most part, run along the lower border of the Pectoralis major to the axillary glands; some few, from the inner side of the breast, perforate the intercostal spaces and empty themselves into the anterior mediastinal glands. The *nerves* are derived from the anterior and lateral cutaneous nerves of the thorax.
THE SURGICAL ANATOMY OF HERNIA.

Dissection (Fig. 757).—For dissection of the parts concerned in inguinal hernia a male subject, free from fat, should always be selected. The body should be placed in the supine position, the abdomen and pelvis raised by means of blocks placed beneath them, and the lower extremities rotated outward, so as to make the parts as tense as possible. If the abdominal walls are flaccid, the cavity of the abdomen should be inflated by an aperture through the umbilicus. An incision should be made along the middle line from the umbilicus to the symphysis pubis, and continued along the front of the scrotum, and a second incision from the anterior superior spine of the ilium to just below the umbilicus. These incisions should divide the integument, and the triangular-shaped flap included between them should be reflected downward and outward, when the superficial fascia will be exposed.

The Superficial Fascia of the Abdomen.—This, over the greater part of the abdominal wall, consists of a single layer of fascia, which contains a variable amount of fat; but as it approaches the groin it is easily divisible into two layers, between which are found the superficial vessels and nerves and the superficial inguinal lymphatic glands.

The superficial layer is thick, areolar in texture, containing adipose tissue in its meshes, the quantity of which varies in different subjects. Below, it passes over Poupart's ligament, and is continuous with the outer layer of the superficial fascia of the thigh. In the male this fascia is continued over the penis and over the outer surface of the cord to the scrotum, where it helps to form the dartos. As it passes to the penis and over the cord to the scrotum it changes its character, becoming thin, destitute of adipose tissue, and of a pale reddish color; and in the scrotum it acquires some involuntary muscular fibres. From the scrotum it may be traced backward, to be continuous with the superficial fascia of the perineum. In the female this fascia is continued into the labia majora.

The hypogastric branch of the ilio-hypogastric nerve perforates the aponeurosis of the External oblique muscle about an inch above and a little to the outer side of the external abdominal ring, and is distributed to the integument of the hypogastric region.

The ilio-inguinal nerve escapes at the external abdominal ring, and is distributed to the integument of the upper and inner part of the thigh, to the scrotum in the male and to the labium in the female.

The superficial epigastric artery arises from the femoral about half an inch below Poupart's ligament, and, passing through the saphenous opening in the fascia lata, ascends on to the abdomen, in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches to the superficial inguinal lymphatic glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric and internal mammary arteries.

The superficial circumflex iliac artery, the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outward, parallel with Poupart's ligament, as far as the crest of the ilium, dividing into branches which supply the superficial inguinal lymphatic glands, the superficial fascia, and the integument, anastomosing with the deep circumflex iliac and with the gluteal and external circumflex arteries.

The superficial external pudic (superior) artery arises from the inner side of the femoral artery close to the preceding vessels, and, after passing through the saphenous opening, courses inward across the spermatic cord, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male, and the labium in the female, anastomosing with branches of the internal pudic.

The Superficial Veins.—The veins accompanying these superficial vessels are
usually much larger than the arteries; they terminate in the internal saphenous vein.

The superficial inguinal lymphatic glands are placed immediately beneath the integument, are of large size, and vary from eight to ten in number. They are divisible into two groups: an upper, disposed irregularly along Poupart's ligament, which receive the lymphatic vessels from the integument of the scrotum, penis, parietes of the abdomen, perineal and gluteal regions, and the mucous membrane of the urethra; and an inferior group, which surround the saphenous opening in the fascia lata, a few being sometimes continued along the saphenous vein to a variable extent. This latter group receive the superficial lymphatic vessels from the lower extremity.

The deep layer of the superficial fascia (fascia of Scarpa) is thinner and more membranous in character than the superficial layer. In the middle line it is intimately adherent to the linea alba; above, it is continuous with the superficial fascia over the rest of the trunk; below, it is connected with the fascia lata (thigh) a little below Poupart's ligament; below and internally, in the male, it is continued over the penis and over the outer surface of the cord to the scrotum, where it helps to form the dartos. From the scrotum it may be traced backward to be continuous with the deep layer of the superficial fascia of the perineum. In the female it is continuous with the labia majora.

The scrotum is a cutaneous pouch which contains the testes and part of the spermatic cords, and into which an inguinal hernia frequently descends (see page 1153).

The Aponeurosis of the External Oblique Muscle.—This is a thin but strong
membranous aponeurosis, the fibres of which are directed obliquely downward and inward. That portion of the aponeurosis which extends between the anterior superior spine of the ilium and the spine of the os pubis is a broad band, folded inward and continuous below with the fascia lata; it is called Poupart's ligament. The portion which is reflected from Poupart's ligament at the spine of the os pubis, along the pectineal line, is called Gimbernat's ligament. From the point of attachment of the latter to the pectineal line a few fibres pass upward and inward, behind the inner pillar of the ring, to the linea alba. They diverge as they ascend, and form a thin, triangular, fibrous band, which is called the triangular ligament of the abdomen. In the aponeurosis of the External oblique, immediately above the crest of the os pubis, is a triangular opening, the external or superficial abdominal ring, formed by the separation of the fibres of the aponeurosis in this situation.

The External or Superficial Abdominal Ring.—Just above and to the outer side of the crest of the os pubis an interval is seen in the aponeurosis of the External oblique, called the external abdominal ring. This aperture is oblique in direction, somewhat triangular in form, and corresponds with the course of the fibres of the aponeurosis. It usually measures from base to apex about an inch, and transversely about half an inch. It is bounded below by the crest of the os pubis; above, by a series of curved fibres, the intercolumnar, which pass across the upper angle of the ring, so as to increase its strength; and on either side, by the margins of the opening in the aponeurosis, which are called the columns or pillars of the ring.

The external pillar, which at the same time is inferior from the obliquity of its direction, is the stronger; it is formed by that portion of Poupart's ligament which is inserted into the spine of the os pubis; it is curved, so as to form a kind of groove, upon which the spermatic cord rests.

The internal or superior pillar is a broad, thin, flat band, which is attached to the front of the body of the os pubis, interlacing with its fellow of the opposite side in front of the symphysis pubis, that of the right side being superficial.

The external abdominal ring gives passage to the spermatic cord in the male and round ligament in the female; it is much larger in men than in women, on account of the large size of the spermatic cord, and hence the great frequency of inguinal hernia in men.

The intercolumnar fibres are a series of curved tendinous fibres which arch across the lower part of the aponeurosis of the External oblique. They have received their name from stretching across between the two pillars of the external ring; they increase the strength of the lower part of the aponeurosis and prevent the divergence of the pillars from one another. They are thickest below, where they are connected to the outer third of Poupart's ligament, and are inserted into the linea alba, describing a curve, with the convexity downward. They are much thicker and stronger at the outer angle of the external ring than internally, and are more strongly developed in the male than in the female. These intercolumnar fibres, as they pass across the external abdominal ring, are themselves connected together by delicate fibrous tissue, thus forming a fascia which, as it is attached to the pillars of the ring, covers it in, and is called the intercolumnar fascia. This intercolumnar fascia is continued downward as a tubular prolongation around the outer surface of the cord and testis, and encloses them in a distinct sheath; hence it is also called the external spermatic fascia. The sac of an inguinal hernia in passing through the external abdominal ring receives an investment from the intercolumnar fascia.

If the finger is introduced a short distance into the external ring, and then, if the limb is extended and rotated outward, the aponeurosis of the External oblique, together with the iliac portion of the fascia lata, will be felt to become tense and the external ring much contracted; if the limb is, on the contrary, flexed upon the pelvis and rotated inward, this aponeurosis will become lax, and the external ring sufficiently enlarged to admit the finger with comparative ease; hence the patient should always be put in the latter position when the taxis is applied for the reduc-
tion of an inguinal hernia, in order that the abdominal walls may be relaxed as much as possible.

The aponeurosis of the External oblique should be removed by dividing it across in the same direction as the external incisions, and reflecting it downward and outward: great care is requisite in separating it from the aponeurosis of the muscle beneath. The lower part of the Internal oblique and the Cremaster are then exposed, together with the inguinal canal, which contains the spermatic cord (Fig. 758). The mode of insertion of Poupart's and Gimbernat's ligaments into the os pubis should also be examined.

**Poupart's ligament**, or the crural arch, is the lower border of the aponeurosis of the External oblique muscle, which extends from the anterior superior spine of the ilium to the spine of the os pubis. From this latter point it is reflected outward to be attached to the pectineal line for about half an inch, forming Gimbernat's ligament. Its general direction is curved downward toward the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction; its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord.

**Gimbernat's ligament** (Fig. 765) is that portion of the External oblique muscle which is reflected downward and outward from the spine of the os pubis to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form, with the base directed outward. Its base or outer margin is concave, thin, and sharp, and lies in contact with the crural sheath, forming the inner boundary of the crural ring (see Fig. 766). Its apex corresponds to the spine of the os pubis. Its posterior margin is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its anterior margin is continuous with Poupart's ligament.

The **triangular ligament of the abdomen** is a band of tendinous fibres, of a triangular shape, which is attached by its apex to the pectineal line, where it is

---

Fig. 758.—Inguinal hernia, showing the Internal oblique, Cremaster, and spermatic canal.
continuous with Gimbernat's ligament. It passes inward beneath the spermatic cord, and expands into a somewhat fan-shaped fascia, lying behind the inner pillar of the external abdominal ring and in front of the conjoined tendon, and interlaces with the ligament of the other side at the linea alba.

The **Internal oblique muscle** has been previously described (page 451). The part which is now exposed is partly muscular and partly tendinous in structure. Those fibres which arise from Poupart's ligament, few in number and paler in color than the rest, arch downward and inward across the spermatic cord, and, becoming tendinous, are inserted, conjointly with those of the Transversalis, into the crest of the os pubis and pectineal line, forming what is known as the conjoined tendon of the Internal oblique and Transversalis. This tendon is inserted immediately behind the external abdominal ring, serving to protect what would otherwise be a weak point in the abdominal wall. Sometimes this tendon is insufficient to resist the pressure from within, and is carried forward in front of the protrusion through the external ring, forming one of the coverings of direct inguinal hernia, or the hernia forces its way through the fibres of the conjoined tendon.

The **Cremaster** is a thin muscular layer composed of a number of fasciculi which arise from the middle of Poupart's ligament at the inner side of the Internal oblique, being connected with that muscle and also occasionally with the Transversalis. It passes along the outer side of the spermatic cord, descends with it through the external ring upon the front and sides of the cord, and forms a series of loops which differ in thickness and length in different subjects. Those at the upper part of the cord are exceedingly short, but they become in succession longer and longer, the longest reaching down as low as the testicle, where a few are inserted into the tunica vaginalis. These loops are united together by areolar tissue, and form a thin covering over the cord and testis, the *fascia cremastica*. The fibres ascend along the inner side of the cord, and are inserted by a small pointed tendon into the crest of the os pubis and front of the sheath of the Rectus muscle.

It will be observed that the origin and insertion of the Cremaster is precisely similar to that of the lower fibres of the Internal oblique. This fact affords an easy explanation of the manner in which the testicle and cord are invested by this muscle. At an early period of foetal life the testis is placed at the lower and back part of the abdominal cavity, but during its descent toward the scrotum, which takes place before birth, it passes beneath the arched border of the Internal oblique. In its passage beneath this muscle some fibres are derived from its lower part which accompany the testicle and cord into the scrotum.

It occasionally happens that the loops of the Cremaster surround the cord, some lying behind as well as in front. It is probable that under these circumstances the testis in its descent passes through, instead of beneath, the fibres of the Internal oblique.

In the descent of an oblique inguinal hernia, which takes the same course as the spermatic cord, the Cremaster muscle forms one of its coverings. This muscle becomes largely developed in cases of hydrocele and large old scrotal hernie. No such muscle exists in the female, except a few fibres on the surface of the round ligament, but an analogous structure is developed in those cases where an oblique inguinal hernia descends beneath the margin of the Internal oblique.

The Internal oblique should be detached from Poupart's ligament, separated from the Transversalis to the same extent as in the previous inclusions, and reflected inward on to the sheath of the Rectus (Fig. 759). The circumflex iliac vessels, which lie between these two muscles, form a valuable guide to their separation.

The **Transversalis muscle** has been previously described (page 453). The part which is now exposed is partly muscular and partly tendinous in structure; this portion arises from the outer third of Poupart's ligament, its fibres curve downward and inward, and are inserted, together with those of the Internal oblique, into the lower part of the linea alba, into the crest of the os pubis and pectineal line, forming what is known as the conjoined tendon of the Internal oblique and
THE FASCIA TRANSVERSA LIS. 1185

Transversalis. Between the lower border of this muscle and Poupart’s ligament a space is left in which is seen the fascia transversalis.

The inguinal or spermatic canal contains the spermatic cord in the male and the round ligament in the female. It is an oblique canal, about an inch and a half in length, directed downward and inward and placed parallel with, and a little above, Poupart’s ligament. It commences above at the internal abdominal ring, which is the point where the cord enters the spermatic canal, and terminates below at the external ring. It is bounded, in front, by the integument and superficial fascia, by the aponeurosis of the External oblique throughout its whole length, and by the Internal oblique for its outer third; behind, by the triangular ligament, the conjoined tendon of the Internal oblique and Transversalis, transversalis fascia, and the subperitoneal fat and peritoneum; above, by the arched fibres of the Internal oblique and Transversalis; below, by the union of the fascia transversalis with Poupart’s ligament. That form of protrusion in which the intestine follows the course of the spermatic cord along the spermatic canal is called oblique inguinal hernia.

The fascia transversalis is a thin aponeurotic membrane which lies between the inner surface of the Transversalis muscle and the peritoneum. It forms part of the general layer of fascia which lines the interior of the abdominal and pelvic cavities, and is directly continuous with the iliac and pelvic fasciae.

In the inguinal region the transversalis fascia is thick and dense in structure, and joined by fibres from the aponeurosis of the Transversalis muscle; but it becomes thin and cellular as it ascends to the Diaphragm. Below, it has the following attachments: external to the femoral vessels it is connected to the posterior margin of Poupart’s ligament, and is there continuous with the iliac fascia. Internal to the vessels it is thin, and attached to the os pubis and pectineal line behind the conjoined tendon, with which it is united; and, corresponding to the points where the femoral vessels pass into the thigh, this fascia descends in front of them, forming the anterior wall of the crural sheath. The spermatic cord

Fig. 758.—Inguinal hernia showing the Transversalis muscle, the transversalis fascia, and the internal abdominal ring.
in the male and the round ligament in the female pass through this fascia; the point where they pass through is called the internal or deep abdominal ring. This opening is not visible externally, owing to a prolongation of the transversalis fascia on these structures, forming the infundibuliform process.

The internal or deep abdominal ring is situated in the transversalis fascia, midway between the anterior superior spine of the ilium and the symphysis pubis, and about half an inch above Poupart’s ligament. It is of an oval form, the extremities of the oval directed upward and downward; it varies in size in different subjects, and is much larger in the male than in the female. It is bounded above and externally by the arched fibres of the Transversalis muscle, below and internally by the deep epigastric vessels. It transmits the spermatic cord in the male and the round ligament in the female. From its circumference a thin, funnel-shaped membrane, the infundibuliform fascia, is continued round the cord and testis, enclosing them in a distinct pouch. When the sac of an oblique inguinal hernia passes through the internal or deep abdominal ring, the infundibuliform process of the transversalis fascia forms one of its coverings.

The Subperitoneal Areolar Tissue.—Between the fascia transversalis and the peritoneum is a quantity of loose areolar tissue. In some subjects it is of considerable thickness and loaded with adipose tissue. Opposite the internal ring it is continued round the surface of the cord, forming a loose sheath for it.

The deep epigastric artery arises from the external iliac artery a few lines above Poupart’s ligament. It at first descends to reach this ligament, and then ascends obliquely along the inner margin of the internal or deep abdominal ring, lying between the transversalis fascia and the peritoneum, and passing upward pierces the transversalis fascia and enters the sheath of the Rectus muscle just below the semilunar fold of Douglas. Consequently the deep epigastric artery bears a very important relation to the internal abdominal ring as it passes obliquely upward and inward from its origin from the external iliac. In this part of its course it lies along the lower and inner margin of the internal ring and beneath the commencement of the spermatic cord. As it winds round the internal abdominal ring it is crossed by the vas deferens in the male and by the round ligament in the female.

The peritoneum, corresponding to the inner surface of the internal ring, presents a well-marked depression, the depth of which varies in different subjects. A thin fibrous band is continued from it along the front of the cord for a variable distance, and becomes ultimately lost. This is the remains of the pouch of peritoneum which, in the foetus, accompanies the cord and testis into the scrotum, the obliteration of which commences soon after birth. In some cases the fibrous band can only be traced a short distance, but occasionally it may be followed, as a fine cord, as far as the upper end of the tunica vaginalis. Sometimes the tube of peritoneum is only closed at intervals and presents a sacculated appearance, or a single pouch may extend along the whole length of the cord, which may be closed above, or the pouch may be directly continuous with the peritoneum by an opening at its upper part.

In the female (in the foetus) the peritoneum is also prolonged in the form of a tubular process for a short distance into the inguinal canal. This process is called the canal of Nuck. It is generally obliterated in the adult, but sometimes it remains perversive even in advanced life. It is analogous to the peritoneal pouch which accompanies the descent of the testis.

INGUINAL HERNIA.

Inguinal hernia is that form of protrusion which makes its way through the abdomen in the inguinal region.

There are two principal varieties of inguinal hernia—external or oblique, and internal or direct.

External or oblique inguinal hernia, the more frequent of the two, takes the
same course as the spermatic cord. It is called external from the neck of the sac being on the outer or iliac side of the deep epigastric artery.

Internal or direct inguinal hernia does not follow the same course as the cord, but protrudes through the abdominal wall on the inner or pubic side of the deep epigastric artery.

**Oblique Inguinal Hernia.**

In oblique inguinal hernia the intestine escapes from the abdominal cavity at the internal ring, pushing before it a pouch of peritoneum, which forms the hernial sac (Fig. 761, A). As it enters the inguinal canal it receives an investment from the subserous areolar tissue, and is enclosed in the infundibuliform process of the transversalis fascia. In passing along the inguinal canal it displaces upward the arched fibres of the Transversalis and Internal oblique muscles, and is surrounded by the fibres of the Cremaster. It then passes along the front of the cord, and escapes from the inguinal canal at the external ring, receiving an investment from the intercolumnar fascia. Lastly, it descends into the scrotum, receiving coverings from the superficial fascia and the integument.

The coverings of this form of hernia, after it has passed through the external ring, are, from without inward, the integument, superficial fascia, intercolumnar fascia, Cremaster muscle, infundibuliform fascia, subserous areolar tissue, and peritoneum.

This form of hernia lies in front of the vessels of the spermatic cord and
seldom extends below the testis, on account of the intimate adhesion of the coverings of the cord to the tunica vaginalis.

The seat of stricture in oblique inguinal hernia is either at the external ring, in the inguinal canal, caused by the fibres of the Internal oblique or Trans-
versalis; or at the internal ring, most frequently in the latter situation. If it is situated at the external ring, the division of a few fibres at one point of its circumference is all that is necessary for the replacement of the hernia. If in the inguinal canal or at the internal ring, it may be necessary to divide the aponeurosis of the External oblique so as to lay open the inguinal canal. In dividing the stricture the direction of the incision should be upward.

When the intestine passes along the spermatic canal and escapes from the external ring into the scrotum, it is called complete oblique inguinal or serotal hernia. If the intestine does not escape from the external ring, but is retained in the inguinal canal, it is called incomplete inguinal hernia, or bubonocele. In each of these cases the coverings which invest it will depend upon the extent to which it descends in the inguinal canal.

There are some other varieties of oblique inguinal hernia depending upon congenital defects in the processus vaginalis. The testicle in its descent from the abdomen into the scrotum is accompanied by a pouch of peritoneum, which about the period of birth becomes shut off from the general peritoneal cavity by a closure of that portion of the pouch which extends from the internal abdominal ring to near the upper part of the testicle, the lower portion of the pouch remaining persistent as the tunica vaginalis. It would appear that this closure commences at two points—viz. at the internal abdominal ring and at the top of the epididymis—and gradually extends until, in the normal condition, the whole of the intervening portion is converted into a fibrous cord. From failure in the completion of this process variations in the relation of the hernial protrusion to the testicle and tunica vaginalis are produced, which constitute distinct varieties of inguinal hernia, and which have received separate names and are of surgical importance. These are congenital, infantile, encysted, and hernia of the funicular process.

Congenital Hernia (Fig. 761, b).—Where the pouch of peritoneum which accompanies the cord and testis in its descent remains patent throughout and is unclosed at any point, the cavity of the tunica vaginalis communicates directly with the peritoneum. The intestine descends along this pouch into the cavity of the tunica vaginalis, which constitutes the sac of the hernia, and the gut lies in contact with the testicle.

Infantile and Encysted Hernia.—Where the pouch of peritoneum is occluded at the internal ring only, and remains patent throughout the rest of its extent, two varieties of oblique inguinal hernia may be produced, which have received the names of infantile and encysted hernia. In the infantile form (Fig. 761, c) the bowel, pressing upon the septum and the peritoneum in its immediate neighborhood, causes it to yield and form a sac, which descends behind the tunica vaginalis, so that in front of the bowel there are three layers of peritoneum, the two layers of the tunica vaginalis and its own sac. In the encysted form (Fig. 761, d) pressure in the same position—namely, at the occluded spot in the pouch—causes the septum to yield and form a sac which projects into and not behind the tunica vaginalis, as in the infantile form, and thus it constitutes a sac within a sac, so that in front of the bowel there are two layers of peritoneum—one layer of the tunica vaginalis and its own sac.

Hernia into the Funicular Process (Fig. 761, e).—Where the pouch of peritoneum is occluded at the lower point only—that is, just above the testicle—the intestine descends into the pouch of peritoneum as far as the testicle, but is prevented from entering the sac of the tunica vaginalis by the septum which has formed between it and the pouch, so that it resembles the congenital form in all respects, except that, instead of enveloping the testicle, that body can be felt below the rupture.

Direct Inguinal Hernia.

In direct inguinal hernia the protrusion makes its way through some part of the abdominal wall internal to the epigastric artery.
At the lower part of the abdominal wall is a triangular space (*Hesselbach's triangle*), bounded externally by the deep epigastric artery covered by peritoneum (*plica epigastrica*), internally by the margin of the Rectus muscle, below by Poupart's ligament. The conjoined tendon is stretched across the inner two-thirds of this space, the remaining portion of the space having only the subperitoneal areolar tissue and the transversalis fascia between the peritoneum and the aponeurosis of the External oblique muscle.

In some cases the hernial protrusion escapes from the abdomen on the outer side of the conjoined tendon, pushing before it the peritoneum, the subserous areolar tissue, and the transversalis fascia. It then enters the inguinal canal, passing along nearly its whole length, and finally emerges from the external ring, receiving an investment from the intercolumnar fascia. The coverings of this form of hernia are precisely similar to those investing the oblique form, with the insignificant difference that the infundibuliform fascia is replaced by a portion derived from the general layer of the fascia transversalis.

In other cases—and this is the more frequent variety—the hernia is either forced through the fibres of the conjoined tendon or the tendon is gradually distended in front of it so as to form a complete investment for it. The intestine then enters the lower end of the inguinal canal, escapes at the external ring lying on the inner side of the cord, and receives additional coverings from the superficial fascia and the integument. This form of hernia has the same coverings as the oblique variety, excepting that the conjoined tendon is substituted for the Cremaster, and the infundibuliform fascia is replaced by a portion derived from the general layer of the fascia transversalis.

The difference between the position of the neck of the sac in these two forms of direct inguinal hernia has been referred, with some probability, to a difference in the relative positions of the obliterated hypogastric artery and the deep epigastric artery. When the course of the obliterated hypogastric artery corresponds pretty nearly with that of the deep epigastric—which is regarded as the normal arrangement—the projection of these arteries toward the cavity of the abdomen produces two fossae in the peritoneum. The bottom of the external fossa of the peritoneum corresponds to the position of the internal abdominal ring, and a hernia which distends and pushes out the peritoneum lining this fossa is an oblique hernia. When, on the other hand, the obliterated hypogastric artery lies considerably to the inner side of the deep epigastric artery, corresponding to the outer margin of the conjoined tendon, the projection of the peritoneum over it (*plica hypogastrica*) divides the triangle of Hesselbach into two parts, so that three depressions will be seen on the inner surface of the lower part of the abdominal wall—viz. an external one, on the outer side of the deep epigastric artery; a middle one, between the deep epigastric and the obliterated hypogastric arteries; and an internal one, on the inner side of the obliterated hypogastric artery. In such a case a hernia may distend and push out the peritoneum forming the bottom of the external fossa, it is an oblique or external inguinal hernia. These fossae are the *inguinal fossae*.

When the hernia distends and pushes out the peritoneum forming the bottom of either the middle or the internal fossa, it is a direct or internal hernia.

The anatomical difference between these two forms of direct or internal inguinal hernia is that, when the hernia protrudes through the middle fossa—that is, the fossa between the deep epigastric and the obliterated hypogastric arteries—it will enter the upper part of the inguinal canal; consequently its coverings will be the same as those of an oblique hernia, with the insignificant difference that the infundibuliform fascia is replaced by a portion derived from the general layer of the fascia transversalis, whereas when the hernia protrudes through the internal fossa it is either forced through the fibres of the conjoined tendon or the tendon is gradually distended in front of it so as to form a complete investment for it. The intestine then enters the lower part of the inguinal canal, and escapes from the external abdominal ring lying on the inner side of the cord.
FEMORAL HERNIA.

This form of hernia has the same coverings as the oblique variety, excepting that the conjoined tendon is substituted for the Cremaster, and the infundibulum-fascia is replaced by a portion derived from the general layer of the fascia transversalis.

The seat of stricture in both varieties of direct hernia is most frequently at the neck of the sac or at the external ring. In that form of hernia which perforates the conjoined tendon it not unfrequently occurs at the edges of the fissure through which the gut passes. In dividing the stricture the incision should in all cases be directed upward. If the hernial protrusion passes into the inguinal canal, but does not escape from the external abdominal ring, it forms what is called incomplete direct hernia. This form of hernia is usually of small size, and in corpulent persons very difficult of detection.

Direct inguinal hernia is of much less frequent occurrence than the oblique, their comparative frequency being, according to Cloquet, as one to five. It occurs far more frequently in men than in women, on account of the larger size of the external ring in the former sex. It differs from the oblique in its smaller size and globular form, dependent most probably on the resistance offered to its progress by the transversalis fascia and conjoined tendon. It differs also in its position, being placed over the os pubis and not in the course of the inguinal canal. The deep epigastric artery runs on the outer or iliac side of the neck of the sac, and the spermatic cord along its external and posterior side, not directly behind it, as in oblique inguinal hernia.

FEMORAL HERNIA.

The dissection of the parts comprised in the anatomy of femoral hernia should be performed, if possible, upon a female subject free from fat. The subject should lie upon its back; a block is first placed under the pelvis, the thigh everted, and the knee slightly bent and retained in this position. An incision should then be made from the anterior superior spinous process of the ilium along Poupart’s ligament to the symphysis pubis; a second incision should be carried transversely across the thigh about six inches beneath the preceding; and these are to be connected together by a vertical one carried along the inner side of the thigh. These several incisions should divide merely the integument; this is to be reflected outward, when the superficial fascia will be exposed.

The superficial fascia forms a continuous layer over the whole of the thigh, consisting of areolar tissue, containing in its meshes much fat, and capable of being separated into two or more layers, between which are found the superficial vessels and nerves. It varies in thickness in different parts of the limb. In the groin it is thick, and the two layers are separated from one another by the superficial inguinal lymphatic glands, the internal saphenous vein, and several smaller vessels. One of these layers, the superficial, is continuous with the superficial fascia of the abdomen.

The superficial layer should be detached by dividing it across in the same direction as the external incisions; its removal will be facilitated by commencing at the lower and inner angle of the space, detaching it at first from the front of the internal saphenous vein, and dissecting it off from the anterior surface of that vessel and its tributaries; it should then be reflected outward in the same manner as the integument. The cutaneous vessels and nerves and superficial inguinal glands are then exposed, lying upon the deep layer of the superficial fascia. These are the internal saphenous vein and the superficial epigastric, superficial circumflex iliac, and superficial external pudic vessels, as well as numerous lymphatics, ascending with the saphenous vein to the inguinal glands.

The internal or long saphenous vein ascends along the inner side of the thigh, and, passing through the saphenous opening in the fascia lata, terminates in the femoral vein about an inch and a half below Poupart’s ligament. This vein

1 In all cases of inguinal hernia, whether oblique or direct, it is proper to divide the stricture directly upward: the reason of this is obvious, for by cutting in this direction the incision is made parallel to the deep epigastric artery—either external to it in the oblique variety, or internal to it in the direct form of hernia—and thus all chance of wounding the vessel is avoided. If the incision was made outward, the artery might be divided if the hernia was direct; and if made inward, it would stand an equal chance of injury if the case was one of oblique inguinal hernia.
receives at the saphenous opening the superficial epigastric, the superficial circumflex iliac, and the superficial external pudic veins.

The superficial external pudic artery (superior) arises from the inner side of the femoral artery, and, after passing through the saphenous opening, courses inward across the spermatic cord, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male and the labium in the female, anastomosing with branches of the internal pudic.

The superficial epigastric artery arises from the femoral about half an inch below Poupart's ligament, and, passing through the saphenous opening in the fascia lata, ascends on to the abdomen, in the superficial fascia covering the external oblique muscle, nearly as high as the umbilicus. It distributes branches to the superficial inguinal lymphatic glands, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric and internal mammary arteries.

The superficial circumflex iliac artery, the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outward, parallel with Poupart's ligament, as far as the crest of the ilium, dividing into branches which supply the superficial inguinal lymphatic glands, the superficial fascia, and the integument of the groin, anastomosing with the deep circumflex iliac, and with the gluteal and external circumflex arteries.

The Superficial Veins.—The veins accompanying these superficial arteries are usually much larger than the arteries: they terminate in the internal or long saphenous vein at the saphenous opening.
The superficial inguinal lymphatic glands, placed immediately beneath the integument, are of large size and vary from eight to ten in number. They are divisible into two groups: an upper, disposed irregularly along Poupart’s ligament, which receive the lymphatic vessels from the integument of the scrotum, penis, parietes of the abdomen, perineal and gluteal regions, and the mucous membrane of the urethra; and an inferior group, which surround the saphenous opening in the fascia lata, a few being sometimes continued along the saphenous vein to a variable extent. This latter group receive the superficial lymphatic vessels from the lower extremity.

The ilio-inguinal nerve arises from the first lumbar nerve. It escapes at the external abdominal ring, and is distributed to the integument of the upper and inner part of the thigh—to the scrotum in the male and to the labium in the female. The size of this nerve is in inverse proportion to that of the ilio-hypogastric. Occasionally it is very small, and ends by joining the ilio-hypogastric: in such cases a branch of the ilio-hypogastric takes the place of the ilio-inguinal, or the latter nerve may be altogether absent. The crural branch of the genito-crural nerve passes along the inner margin of the Psoas muscle, beneath Poupart’s ligament, into the thigh, entering the sheath of the femoral vessels, and lying superficial and a little external to the femoral artery. It pierces the anterior layer of the sheath of the vessels, and, becoming superficial by passing through the fascia lata, it supplies the skin of the anterior aspect of the thigh as far as midway between the pelvis and knee. On the front of the thigh it communicates with the outer branch of the middle cutaneous nerve, derived from the anterior crural.

The deep layer of the superficial fascia is a very thin fibrous layer, best marked on the inner side of the long saphenous vein and below Poupart’s ligament. It is placed beneath the subcutaneous vessels and nerves, and upon the surface of the fascia lata, to which it is intimately adherent at the lower margin of Poupart’s ligament. It covers the saphenous opening in the fascia lata, is closely united to its circumference, and is connected to the sheath of the femoral vessels corresponding to its under surface. The portion of fascia covering this aperture is perforated by the internal saphenous vein and by numerous blood- and lymphatic vessels; hence it has been termed the cribriform fascia, the openings for these vessels having been likened to the holes in a sieve. The cribriform fascia adheres closely both to the superficial fascia and to the fascia lata, so that it is described by some anatomists as a part of the fascia lata, but it is usually considered (as in this work) as belonging to the superficial fascia. It is not till the cribriform fascia has been cleared away that the saphenous opening is seen, so that this opening does not in ordinary cases exist naturally, but is the result of dissection. A femoral hernia in passing through the saphenous opening receives the cribriform fascia as one of its coverings.

The deep layer of superficial fascia, together with the cribriform fascia, having been removed, the fascia lata is exposed.

The Fascia Lata has been already described with the muscles of the front of the thigh (page 506). At the upper and inner part of the thigh, a little below Poupart’s ligament, a large oval-shaped aperture is observed after the superficial fascia has been cleared away; it transmits the internal saphenous vein and other smaller vessels, and is called the saphenous opening. In order the more correctly to consider the mode of formation of this aperture, the fascia lata in this part of the thigh is described as consisting of two portions, an iliac portion and a pubic portion.

The iliac portion is all that part of the fascia lata on the outer side of the saphenous opening. It is attached externally to the crest of the ilium and its anterior superior spine; to the whole length of Poupart’s ligament as far internally as the spine of the os pubis; and to the pectineal line in conjunction with Gimbernat’s ligament. From the spine of the os pubis it is reflected downward and outward, forming an arched margin, the outer boundary or falceform process or superior cornu of the saphenous opening. This margin overlies and is adherent to the anterior layer of the sheath of the femoral vessels; to its edge is attached
cribriform fascia, and below it is continuous with the pubic portion of the fascia lata.

The pubic portion of the fascia lata is situated at the inner side of the saphenous opening: at the lower margin of this aperture it is continuous with the iliac portion: traced upward, it covers the surface of the Pectineus, Adductor longus, and Gracilis muscles; and, passing behind the sheath of the femoral vessels, to which it is closely united, is continuous with the sheath of the Psoas and Iliacus muscles, and is attached above to the ilio-pectineal line, where it becomes continuous with the fascia covering the Iliacus muscle. From this description it may be observed that the iliac portion of the fascia lata passes in front of the femoral vessels and the pubic portion behind them, so that an apparent aperture consequently exists between the two, through which the internal saphenous joins the femoral vein.

The Saphenous Opening is an oval-shaped aperture measuring about an inch and a half in length and half an inch in width. It is situated at the upper and inner part of the front of the thigh, below Poupart's ligament, and is directed obliquely downward and outward.

Its outer margin is of a semilunar form, thin, strong, sharply defined, and lies on a plane considerably anterior to the inner margin. If this edge is traced upward, it will be seen to form a curved elongated process, the falciform process or superior cornu, which ascends in front of the femoral vessels, and, curving inward, is attached to Poupart's ligament and to the spine of the os pubis and pectineal line, where it is continuous with the pubic portion. If traced downward, it is found continuous with another curved margin, the concavity of which is directed upward and inward: this is the inferior cornu of the saphenous

Fig. 763.—Femoral hernia, showing fascia lata and saphenous opening.
opening, and is blended with the pubic portion of the fascia lata covering the Pectineus muscle.

The inner boundary of the opening is on a plane posterior to the outer margin and behind the level of the femoral vessels; it is much less prominent and defined than the outer, from being stretched over the subjacent Pectineus muscle. It is through the saphenous opening that a femoral hernia passes after descending along the crural canal.

If the finger is introduced into the saphenous opening while the limb is moved in different directions, the aperture will be found to be greatly constricted on extending the limb or rotating it outward, and to be relaxed on flexing the limb.

Fig. 764.—Femoral hernia. Iliac portion of fascia lata removed, and sheath of femoral vessels and femoral canal exposed.

and inverting it: hence the necessity for placing the limb in the latter position in employing the taxis for the reduction of a femoral hernia.

The iliac portion of the fascia lata, but not its falciform process, should now be removed by detaching it from the lower margin of Poupart’s ligament, carefully dissecting it from the subjacent structures, and turning it inward, when the sheath of the femoral vessels is exposed, descending beneath Poupart’s ligament (Fig. 764).

Poupart’s Ligament, or the Crural Arch, is the lower border of the aponeurosis of the External oblique muscle, which extends from the anterior superior spine of the ilium to the spine of the os pubis. From this latter point it is reflected outward, to be attached to the pectineal line for about half an inch, forming Gimbernat’s ligament. Its general direction is curved downward toward the thigh, where it is continuous with the fascia lata. Its outer half is rounded and oblique in direction. Its inner half gradually widens at its attachment to the os pubis, is more horizontal in direction, and lies beneath the spermatic cord. Nearly the
whole of the space included between the crural arch and innominate bone is filled in by the parts which descend from the abdomen into the thigh. The outer half of the space is occupied by the Iliacus and Psoas muscles, together with the external cutaneous and anterior crural nerves. The pubic half of the space is occupied by the femoral vessels included in their sheath, a small oval-shaped interval existing between the femoral vein and the inner wall of the sheath, which is occupied merely by a little loose areolar tissue, a few lymphatic vessels, and occasionally by a small lymphatic gland: this is the crural ring, through which the gut descends in femoral hernia.

**Gimbernat’s Ligament** (Fig. 766) is that part of the aponeurosis of the External oblique muscle which is reflected downward and outward from the spine of the os pubis, to be inserted into the pectineal line. It is about half an inch in length, larger in the male than in the female, almost horizontal in direction in the erect posture, and of a triangular form, with the base directed outward. Its base, or outer margin, is concave, thin, and sharp, and lies in contact with the crural sheath. Its apex corresponds to the spine of the os pubis. Its *posterior margin* is attached to the pectineal line, and is continuous with the pubic portion of the fascia lata. Its *anterior margin* is continuous with Poupart’s ligament.

**Crural Sheath.**—The femoral or crural sheath is a continuation downward of the fasciae that line the abdomen, the transversalis fascia passing down in front of the femoral vessels, and the iliac fascia descending behind them; these fasciae are directly continuous on the iliac side of the femoral artery, but a small space exists between the femoral vein and the point where they are continuous on the pubic side of that vessel, which constitutes the femoral or crural canal. The
femoral sheath is closely adherent to the contained vessels about an inch below the saphenous opening, being blended with the areolar sheath of the vessels, but opposite Poupart's ligament it is much larger than is required to contain them; hence the funnel-shaped form which it presents. The outer border of the sheath is perforated by the genito-crural nerve. Its inner border is pierced by the internal saphenous vein and numerous lymphatic vessels. In front it is covered by the iliac portion of the fascia lata; and behind it is the pubic portion of the same fascia.

If the anterior wall of the sheath is removed, the femoral artery and vein are seen lying side by side, a thin septum separating the two vessels, while another septum may be seen lying just internal to the vein, and cutting off a small space between the vein and the inner wall of the sheath. The septa are stretched between the anterior and posterior walls of the sheath, so that each vessel is enclosed in a separate compartment. The interval left between the vein and the inner wall of the sheath is not filled up by any structure, excepting a little loose areolar tissue, a few lymphatic vessels, and occasionally by a small lymphatic

gland: this is the femoral or crural canal, through which the intestine descends in femoral hernia.

**Deep Crural Arch.**—Passing across the front of the crural sheath on the abdominal side of Poupart's ligament, and closely connected with it, is a thickened band of fibres called the *deep crural arch*. It is apparently a thickening of the fascia transversalis, joining externally to the centre of Poupart's ligament, and arching across the front of the crural sheath, to be inserted by a broad attachment into the pectineal line behind the conjoined tendon. In some subjects this structure is not very prominently marked, and not unfrequently it is altogether wanting.

The *crural canal* is the narrow interval between the femoral vein and the inner wall of the crural sheath. It exists as a distinct canal only when the sheath has been separated from the vein by dissection or by the pressure of a hernia or tumor. Its length is from a quarter to half an inch, and it extends from Gimbernat's ligament to the upper part of the saphenous opening.

Its *anterior wall* is very narrow, and formed by a continuation downward of the fascia transversalis, under Poupart's ligament, covered by the falciform process of the fascia lata.
Its posterior wall is formed by a continuation downward of the iliac fascia covering the pubic portion of the fascia lata.

Its outer wall is formed by the fibrous septum separating it from the inner side of the femoral vein.

Its inner wall is formed by the junction of the processes of the transversalis and iliac fasciae, which form the inner side of the femoral sheath, and lies in contact at its commencement with the outer edge of Gimbernat's ligament.

This canal has two orifices—an upper one, the femoral or crural ring, closed by the septum crurale; and a lower one, the saphenous opening, closed by the cribriform fascia.

The femoral or crural ring (Fig. 766) is the upper opening of the femoral canal, and leads into the cavity of the abdomen. It is bounded in front by Poupart's ligament and the deep crural arch; behind, by the os pubis, covered by the Pectineus muscle and the pubic portion of the fascia lata; internally, by the base of Gimbernat's ligament, the conjoined tendon, the transversalis fascia, and the deep crural arch; externally, by the fibrous septum lying on the inner side of the femoral vein. The femoral ring is of an oval form; its long diameter, directed transversely, measures about half an inch, and it is larger in the female than in the male, which is one of the reasons of the greater frequency of femoral hernia in the former sex.

Position of Parts around the Ring.—The spermatic cord in the male and round ligament in the female lie immediately above the anterior margin of the femoral ring, and may be divided in an operation for femoral hernia if the incision for the relief of the stricture is not of limited extent. In the female this is of little importance, but in the male the spermatic artery and vas deferens may be divided.

The femoral vein lies on the outer side of the ring.

The deep epigastric artery in its passage upward and inward from the external iliac artery passes across the upper and outer angle of the crural ring, and is consequently in danger of being wounded if the stricture is divided in a direction upward and outward.

The communicating branch between the deep epigastric and obturator lies in front of the ring.

The circumference of the ring is thus seen to be bounded by vessels in every part, excepting internally and behind. It is in the former position that the stricture is divided in cases of strangulated femoral hernia.

The obturator artery, when it arises by a common trunk with the deep epigastric, which occurs once in every three subjects and a half, bears a very important relation to the crural ring. In some cases it descends on the inner side of the external iliac vein to the obturator foramen, and will consequently lie on the outer side of the crural ring, where there is no danger of its being wounded in the operation for dividing the stricture in femoral hernia (see Fig. 373, page 623, fig. A). Occasionally, however, the obturator artery curves along the free margin of Gimbernat's ligament in its passage to the obturator foramen; it would consequently skirt along the greater part of the circumference of the crural ring, and could hardly avoid being wounded in the operation (see Fig. 373, page 623, fig. B).

Septum Crurale.—The femoral ring is closed by a layer of condensed areolar tissue called, by J. Cloquet, the septum crurale. This serves as a barrier to the protrusion of a hernia through this part. Its upper surface is slightly concave (fovea femoralis), and supports a small lymphatic gland by which it is separated from the subserous areolar tissue and peritoneum. Its under surface is turned toward the femoral canal. The septum crurale is perforated by numerous apertures for the passage of lymphatic vessels connecting the deep inguinal lymphatic glands with those surrounding the external iliac artery.

The size of the femoral canal, the degree of tension of its orifices, and consequently the degree of constriction of a hernia, vary according to the position of the limb. If the leg and thigh are extended, abducted, or everted, the femoral
FEMORAL HERNIA.

1199
canal and its orifices are rendered tense from the traction on these parts by Poupart’s ligament and the fascia lata, as may be ascertained by passing the finger along the canal. If, on the contrary, the thigh is flexed upon the pelvis, and at the same time adducted and rotated inward, the femoral canal and its orifices become considerably relaxed; for this reason the limb should always be placed in the latter position when the application of the taxis is made in attempting the reduction of a femoral hernia.

The subperitoneal areolar tissue is continuous with the subserous areolar tissue of surrounding parts. It is usually thickest and most fibrous where the iliac vessels leave the abdominal cavity. It covers over the small interval (crural ring) on the inner side of the femoral vein. In some subjects it contains a considerable amount of adipose tissue. In such cases, where it is protruded forward in front of the sac of a femoral hernia, it may be mistaken for a portion of omentum. The peritoneum lining the portion of the abdominal wall between Poupart’s ligament and the brim of the pelvis is similar to that lining any other portion of the abdominal wall, being very thin. It has here no natural aperture for the escape of intestine.

Descent of the Hernia.—From the preceding description it follows that the femoral ring must be a weak point in the abdominal wall: hence it is that when violent or long-continued pressure is made upon the abdominal viscera a portion of intestine may be forced into it, constituting a femoral hernia; and the changes in the tissues of the abdomen which are produced by pregnancy, together with the larger size of this aperture in the female, serve to explain the frequency of this form of hernia in women.

When a portion of the intestine is forced through the femoral ring, it carries before it a pouch of peritoneum, which forms what is called the hernial sac; it receives an investment from the subserous areolar tissue and from the septum crurale, and descends vertically along the crural canal in the inner compartment of the sheath of the femoral vessels as far as the saphenous opening; at this point it changes its course, being prevented from extending farther down the sheath on account of the narrowing of the sheath and its close contact with the vessels, and also from the close attachment of the superficial fascia and crural sheath to the lower part of the circumference of the saphenous opening; the tumor is consequently directed forward, pushing before it the cribiform fascia, and then curves upward on to the falciiform process of the fascia lata and lower part of the tendon of the External oblique, being covered by the superficial fascia and integument. While the hernia is contained in the femoral canal it is usually of small size, owing to the resisting nature of the surrounding parts; but when it has escaped from the saphenous opening into the loose areolar tissue of the groin, it becomes considerably enlarged. The direction taken by a femoral hernia in its descent is at first downward, then forward and upward; this should be borne in mind, as in the application of the taxis for the reduction of a femoral hernia pressure should be directed in the reverse order.

Coverings of the Hernia.—The coverings of a femoral hernia, from within outward, are—peritoneum, subserous areolar tissue, the septum crurale, crural sheath, cribiform fascia, superficial fascia, and integument.1

Varieties of Femoral Hernia.—If the intestine descends along the femoral canal only as far as the saphenous opening, and does not escape from this aperture, it is called incomplete femoral hernia. The small size of the protrusion in this form of hernia, on account of the firm and resisting nature of the canal in which it is contained, renders it an exceedingly dangerous variety of the disease, from the

1 Sir Astley Cooper has described an investment for femoral hernia, under the name of “fascia propria,” lying immediately external to the peritoneal sac, but frequently separated from it by more or less adipose tissue. Surgically, it is important to remember the existence (at any rate, the occasional existence) of this layer, on account of the ease with which an inexperienced operator may mistake the fascia for the peritoneal sac and the contained fat for omentum. Anatomically, this fascia appears identical with what is called in the text “subserous areolar tissue,” the areolar tissue being thickened and caused to assume a membranous appearance by the pressure of the hernia.
extreme difficulty of detecting the existence of the swelling, especially in corpulent subjects. The coverings of an incomplete femoral hernia would be, from without inward, integument, superficial fascia, falciform process of fascia lata, crural sheath, septum crurale, subserous areolar tissue, and peritoneum. When, however, the hernial tumor protrudes through the saphenous opening and directs itself forward and upward, it forms a complete femoral hernia. Occasionally the hernial sac descends on the iliac side of the femoral vessels or in front of these vessels, or even sometimes behind them.

The seat of stricture of a femoral hernia varies: it may be in the peritoneum at the neck of the hernial sac; in the greater number of cases it would appear to be at the point of junction of the falciform process of the fascia lata with the lunated edge of Gimbernat's ligament, or at the margin of the saphenous opening in the thigh. The stricture should in every case be divided in a direction upward and inward, and the extent necessary in the majority of cases is about two or three lines. By these means all vessels or other structures of importance in relation with the neck of the hernial sac will be avoided.
SURGICAL ANATOMY OF THE ISCHIO-RECTAL REGION AND PERINÆUM.

Dissection.—The student should select a well-developed muscular subject, free from fat, and the dissection should be commenced early, in order that the parts may be examined in as recent a state as possible. A staff having been introduced into the bladder and the subject placed in the position shown in Fig. 767, the scrotum should be raised upward, and retained in that position, and the rectum moderately distended with tow.

The space which is now to be examined corresponds to the inferior aperture or outlet of the pelvis. Its deep boundaries are, in front, the pubic arch and subpubic ligament; behind, the tip of the coccyx; and on each side, the rami of the pubes and ischium, the tuberosities of the ischium, and great sacrosciatic ligaments. The space included by these boundaries is somewhat lozenge-shaped, and is limited on the surface of the body by the scrotum in front, by the buttocks behind, and on each side by the inner side of the thighs. A line drawn transversely between the anterior part of the tuberosity of the ischium on each side, in front of the anus, divides this space into two portions. The anterior portion contains the penis and urethra, and is called the perinæum. The posterior portion contains the termination of the rectum, and is called the ischio-rectal region.

THE ISCHIO-RECTAL REGION.

The ischio-rectal region corresponds to the portion of the outlet of the pelvis situated immediately behind the perinæum: it contains the termination of the rectum and a deep fossa, filled with fat, on each side of the intestine, between it and the tuberosity of the ischium: this is called the ischio-rectal fossa.

The ischio-rectal region presents in the middle line the aperture of the anus: around this orifice the integument is thrown into numerous folds, which are obliterated on distension of the intestine. The integument is of a dark color, continuous with the mucous membrane of the rectum, and provided with numerous follicles, which occasionally inflame and suppurate, and may be mistaken for fistulae. The veins around the margin of the anus are occasionally much dilated, forming a number of hard pendent masses, of a dark bluish color, covered partly by mucous membrane and partly by the integument. These tumors constitute the disease called external piles.

Dissection (Fig. 767).—Make an incision through the integument, along the median line, from the base of the scrotum to the anterior extremity of the anus: carry it round the margins of this aperture to its posterior extremity, and continue it backward to about an inch behind the tip of the coccyx. A transverse incision should now be carried across the base of the scrotum, joining the anterior extremity of the preceding; a second, carried in the same direction, should be made in front of the anus; and a third at the posterior extremity of the first incision. These incisions should be sufficiently extensive to enable the dissector to raise the integument from the inner side of the thighs. The flaps of skin corresponding to the ischio-rectal region should now be removed. In dissecting the integument from this region great care is required, otherwise the Corrugator cutis ani and External sphincter will be removed, as they are intimately adherent to the skin.

The superficial fascia is exposed on the removal of the skin: it is very thick, areolar in texture, and contains much fat in its meshes. In it are found ramifying two or three cutaneous branches of the small sciatic nerve; these turn round the inferior border of the Gluteus maximus and are distributed to the integument around the anus.

76
In this region, and connected with the lower end of the rectum, are four muscles: the Corrugator cutis ani; the two Sphincters, External and Internal; and the Levator ani.

These muscles have been already described (see pages 458 and 459).

The ischio-rectal fossa is situated between the end of the rectum and the tuberosity of the ischium on each side. It is triangular in shape; its base, directed to the surface of the body, is formed by the integument of the ischio-rectal region; its apex, directed upward, corresponds to the point of division of the obturator fascia and the thin membrane given off from it, which covers the outer surface of the Levator ani (ischio-rectal or anal fascia). Its dimensions are about an inch in breadth at the base and about two inches in depth, being deeper behind than in front. It is bounded, internally, by the Sphincter ani, Levator ani, and Coccygeus muscles; externally, by the tuberosity of the ischium and the obturator fascia, which covers the inner surface of the Obturator internus muscle; in front, it is limited by the line of junction of the superficial and deep perineal fasciae; and behind, by the margin of the Gluteus maximus and the great sacro-sciatic ligament. This space is filled with a large mass of adipose tissue, which explains the frequency with which abscesses in the neighborhood of the rectum burrow to a considerable depth.

If the subject has been injected, on placing the finger on the outer wall of this fossa the internal pudic artery, with its accompanying veins and nerve, will be felt about an inch and a half above the margin of the ischiatic tuberosity, but approaching nearer the surface as they pass forward along the inner margin of the pubic arch. These structures are enclosed in a sheath (canal of Alcock) formed by the obturator fascia, the pudic nerve lying below the artery (Fig. 374). Crossing the space transversely, about its centre are the inferior hemorrhoidal vessels and nerves, branches of the internal pudic; they are distributed to the integument of the anus and to the muscles of the lower end of the rectum. These vessels are occasionally of large size, and may give rise to troublesome haemorrhage when divided in the operation of lithotomy or of fistula in ano. At the back part of this space may be seen a branch of the fourth sacral nerve, and, at the fore part of the space the superficial perineal vessels and nerves can be seen for a short distance.

THE PERINEUM IN THE MALE.

The perineal space is of a triangular form; its deep boundaries are limited, laterally, by the rami of the pubic bones and ischia, meeting in front at the pubic arch; behind, by an imaginary transverse line extending between the tuberosities of the ischia. The lateral boundaries are, in the adult, from three inches to three inches and a half in length, and the base from two to three inches and a half in breadth, the average extent of the space being two inches and three-quarters.

The variations in the diameter of this space are of extreme interest in connection with the operation of lithotomy and the extraction of a stone from the cavity of the bladder. In those cases where the tuberosities of the ischia are near together it would be necessary to make the incisions in the lateral operation of lithotomy less oblique than if the tuberosities were widely separated, and the perineal space consequently wider. The perineum is subdivided by the median raphe into two equal parts. Of these, the left is the one in which the operation of lithotomy is performed.

In the middle line the perineum is convex, and corresponds to the bulb of the urethra. The skin covering it is of a dark color, thin, freely movable upon the subjacent parts, and covered with sharp crisp hairs, which should be removed before the dissection of the part is commenced. In front of the anus a prominent line commences, the raphe, continuous in front with the raphe of the scrotum.

Upon removing the skin and superficial structures from this region, in the manner shown in Fig. 767, a plane of fascia will be exposed, covering in the triangular space and stretching across from one ischio-pubic ramus to the other. This is the deep layer of the superficial fascia or fascia of Colles. It has already
been described (page 460). It is a layer of considerable strength, and encloses and covers a space in which are contained muscles, vessels, and nerves. It is continuous in front with the dartos of the scrotum; on each side it is firmly attached to the margin of the ischio-pubic ramus and to the tuberosity of the ischium; and posteriorly it curves down behind the Transversus perinei muscles to join the lower margin of the deep perineal fascia.

It is between this layer of fascia and the next layer, the superficial layer of the deep perineal fascia, that extravasation of urine most frequently takes place in cases of rupture of the urethra. The superficial layer of the deep perineal fascia (see page 463) is also attached to the ischio-pubic rami, and in front to the subpubic ligament. It is clear, therefore, that when extravasation of fluid takes place between these two layers, it cannot pass backward, because the two layers are continuous with each other around the Transversus perinei muscles; it cannot extend laterally, on account of the connection of both these layers to the rami of the os pubis and ischium; it cannot find its way into the pelvis, because the opening into this cavity is closed by the deep perineal fascia; and therefore, so long as these two layers remain intact, the only direction in which the fluid can make its way is forward into the areolar tissue of the scrotum and penis, and from thence on to the anterior wall of the abdomen.

When the deep layer of the superficial fascia is removed, a space is exposed between this fascia and the deep perineal fascia in which are contained the peri-
the lower layer. The dorsal nerve of the penis is also contained within the two layers, accompanying the dorsal artery along the ischio-pubic ramus, and with it piercing the anterior layer and the suspensory ligament to be distributed to the penis.

The Accelerator urine and Erector penis should now be removed, when the deep perineal fascia will be exposed, stretching across the front part of the outlet of the pelvis. The urethra is seen perforating its centre just behind the bulb, and on each side is the crus penis, connecting the corpus cavernosum with the rami of the ischium and os pubis.

The deep perineal fascia (triangular ligament), which has already been described (see page 463), consists of two layers, the inferior or superficial layer of which, sometimes called the anterior layer of the triangular ligament, is now exposed. It is united to the superior or deep layer behind, but is separated in front by a subfascial space, in which are contained certain structures.

The superficial layer of the deep perineal fascia consists of a strong fibrous membrane, the fibres of which are disposed transversely, which stretches across from one ischio-pubic ramus to the other and completely fills in the pubic arch; it is attached in front to the subpubic ligament, except just in the centre, where a small interspace is left for the dorsal vein of the penis. In the erect position of the body it is almost horizontal. It is perforated by the urethra in the middle line, and on each side by the ducts of Cowper's glands. It is pierced also by the dorsal artery of the penis close to the base of the ligament; by the artery to the corpus cavernosum more anteriorly and in the opposite direction, close to the lateral margin of the ligament; and by the artery to the bulb also from above downward in front of the opening for Cowper's duct. The dorsal nerve of the penis also passes through the ligament in company with the artery of the same name. The crura penis are exposed, lying superficial to this ligament. They will be seen to be attached by blunt-pointed processes to the rami of the os pubis and ischium, in front of the tuberocities, and passing forward and inward, joining to form the body of the penis. In the middle line is the bulb and corpus spongiosum, exposed by the removal of the Accelerator urine muscle.
If the superficial layer of the deep perineal fascia is detached on either side, the deep perineal interspace will be exposed and the following parts will be seen between it and the deep layer of the fascia: the subpubic ligament in front, close to the symphysis pubis; the dorsal vein of the penis; the membranous portion of the urethra and the Compressor urethrae muscle; Cowper's glands and their ducts; the dorsal artery and the dorsal nerve of the penis; the artery and nerve of the bulb and a plexus of veins.

The superior or deep layer of the deep perineal fascia is derived from the obturator fascia or is continuous with it along the pubic arch. Behind, it joins with the superficial layer of the deep perineal fascia and is continuous with the anal fascia. Above it is the recto-vesical fascia, separated from it on each side by the anterior fibres of the Levator ani, but in the median line these two layers of fascia are continuous and form a median septum, in consequence of the recto-vesical fascia dipping down to join the deep layer of the deep perineal fascia. Thus on each side of the middle line, beneath this fascia, is a little interspace in which is contained the anterior fibres of the Levator ani (Levator prostate). It is bounded, below, by the deep layer of the deep perineal fascia; above, by the recto-vesical fascia, and is separated internally from the space on the other side by the median septum. The deep layer of the deep perineal fascia is pierced by the urethra, and is continued backward around the posterior part of the membranous portion of the urethra and the outer surface of the prostate gland.

The Compressor urethrae has already been described (page 404). In addition to this muscle and immediately beneath it circular muscular fibres surround the membranous portion of the urethra from the bulb in front to the prostate behind, and are continuous with the muscular fibres of the bladder. These fibres are involuntary.

Cowper's glands are situated immediately below the membranous portion of the urethra, close behind the bulb, and below the artery of the bulb.

The dorsal artery and dorsal nerve of the penis are placed along the inner margin of the pubic arch (pages 623 and 861).

The artery of the bulb passes transversely inward, from the internal pudic along the base of the triangular ligament, between its two layers of fascia,
accompanied by a branch of the pudic nerve (page 861). If the posterior layer of the deep perineal fascia is removed and the crus penis of one side detached from the bone, the under or perineal surface of the Levator ani is brought fully into view. This muscle, with the triangular ligament in front and the Coccygeus and Pyriformis behind, closes the outlet of the pelvis.

The Levator ani and Coccygeus muscles have already been described (page 459).

**Position of the Viscera at the Outlet of the Pelvis.**—Divide the central tendinous point of the perineum, separate the rectum from its connections by dividing the fibres of the Levator ani, which descend upon the sides of the prostate gland, and draw the gut backward toward the coccyx, when the under surface of the prostate gland, the neck and base of the bladder, the vesiculae seminales, and the vasa deferentia will be exposed.

The **Prostate Gland** is a pale, firm, glandular body which is placed immediately in front of the neck of the bladder around the commencement of the urethra. It is placed in the pelvic cavity, behind and below the symphysis pubis, posterior to the deep perineal fascia, and rests upon the rectum, through which it may be distinctly felt, especially when enlarged. In shape and size it resembles a chestnut. Its base is directed backward toward the neck of the bladder. Its apex is directed forward to the deep perineal fascia, which it touches.

Its posterior surface is smooth, marked by a slight longitudinal furrow, and rests on the rectum, to which it is connected by areolar tissue. Its anterior surface is flattened, marked by a slight longitudinal furrow, and placed about three-quarters of an inch below the pubic symphysis. It measures about an inch and a half in its transverse diameter at the base, an inch in its antero-posterior diameter, and three-quarters of an inch in depth. Hence the greatest extent of incision that can be made in it without dividing its substance completely across is obliquely backward and outward. This is the direction in which the incision is made in it in the lateral operation of lithotomy.

Behind the prostate is the posterior surface of the neck and base of the bladder, a small triangular portion of the bladder being seen, bounded, in front, by the prostate gland; behind, by the recto-vesical fold of the peritoneum; on each side, by the vesicula seminalis and the vas deferens. It is separated from direct contact...
THE FEMALE PERINEUM.

with the rectum by the recto-vesical fascia. The relation of this portion of the bladder to the rectum is of extreme interest to the surgeon. In cases of retention of urine this portion of the organ is found projecting into the rectum, between three and four inches from the margin of the anus, and may be easily perforated without injury to any important parts: this portion of the bladder is, consequently, occasionally selected for the performance of the operation of tapping the bladder.

Surgical Anatomy.—The student should consider the position of the various parts in reference to the lateral operation of lithotomy. This operation is performed on the left side of the perineum, as it is most convenient for the right hand of the operator. A staff having been introduced into the bladder, the first incision is commenced midway between the anus and the back of the scrotum (i. e. in an ordinary adult perineum about an inch and a half in front of the anus) a little on the left side of the raphe, and carried obliquely backward and outward to midway between the anus and tuberosity of the ischium. The incision divides the integument and superficial fascia, the inferior haemorrhoidal vessels and nerves, and the superficial and transverse perineal vessels. If the forefinger of the left hand is thrust upward and forward into the wound, pressing at the same time the rectum inward and backward, the staff may be felt in the membranous portion of the urethra. The finger is fixed upon the staff, and the structures covering it are divided with the point of the knife, which must be directed along the groove toward the bladder, the edge of the knife being turned outward and backward, dividing in its course the membranous portion of the urethra and part of the left lobe of the prostate gland to the extent of about an inch. The knife is then withdrawn, and the forefinger is introduced over the finger into the bladder. If the stone is very large, the opposite side of the prostate may be noted before the forceps is introduced: the finger is now withdrawn, and the blades of the forceps opened and made to grasp the stone, which must be extracted by slow and cautious unifying movements.

Parts Divided in the Operation.—The various structures divided in this operation are as follows: the integument, superficial fascia, inferior haemorrhoidal vessels and nerves, and probably the superficial perineal vessels and nerves, the posterior fibres of the Accelerator urinæ, the Transversus perinei muscle and artery, the deep perineal fascia, the anterior fibres of the Levator ani. part of the Compressor urethrae, the membranous and prostatic portions of the urethra, and part of the prostate gland.

Parts to be Avoided in the Operation.—In making the necessary incisions in the perineum for the extraction of a calculus the following parts should be avoided: The primary incision should not be made too near the middle line, for fear of wounding the bulb of the corpus spongiosum or the rectum, nor too far externally, otherwise the pudendal may be implicated as it ascends along the inner border of the pubis arch. If the incisions are carried too far forward, the artery of the bulb may be divided; if carried too far backward, the entire breadth of the prostate and neck of the bladder may be cut through, which allows the urine to become infiltrated behind the pelvic fascia into the loose areolar tissue between the bladder and rectum, instead of escaping externally; diffuse inflammation is consequently set up, and peritonitis, from the close proximity of the recto-vesical peritoneal fold, is the result. If, on the contrary, the prostate is divided in front of the base of the gland, the urine makes its way externally, and there is less danger of infiltration taking place.

During the operation it is of great importance that the finger should be passed into the bladder before the staff is removed; if this is neglected, and if the incision made in the prostate and neck of the bladder is too small, great difficulty may be experienced in introducing the finger afterward; and in the child, where the connections of the bladder to the surrounding parts are very loose, the force made in the attempt is sufficient to displace the bladder upward into the abdomen, out of the reach of the operator. Such a proceeding has not unfrequently occurred, producing the most embarrassing results and total failure of the operation.

It is necessary to bear in mind that the arteries in the perineum occasionally take an abnormal course. Thus the artery of the bulb, when it arises, as sometimes happens, from the pudic opposite the tuber ischii, is liable to be wounded in the operation for lithotomy in its passage forward to the bulb. The necessary pudic may be divided near the posterior border of the prostate gland, if this is completely cut across; and the prostatic veins, especially in people advanced in life, are of large size, and give rise, when divided, to troublesome haemorrhage.

THE FEMALE PERINEUM.

The female perineum presents certain differences from that of the male, in consequence of the whole of the structures which constitute it being perforated in the middle line by the vulvo-vaginal passage.

The superficial fascia, as in the male, consists of two layers, of which the superficial one is continuous with the superficial fascia over the rest of the body, and the deep layer, corresponding to the fascia of Colles in the male, is like it attached to the ischio-pubic ramus, and in front is continued forward through
the labia majora to the inguinal region. It is of less extent than the male, in consequence of being perforated by the aperture of the vulva.

On removing this fascia the muscles of the female perineum, which have already been described (page 464), are exposed. The Sphincter vaginae, corresponding to the Accelerator urinæ in the male, consists of an attenuated plane of fibres, forming an orbicular muscle around the orifice of the vagina, instead of being united in a median raphe, as in the male. The Erector clitoridis is proportionately reduced in size, but differs in no other respect, and the Transversus perinei is similar to the muscle of the same name in the male.

The deep perineal fascia is not so strongly marked as in the male. It transmits the urethra, and is wide, separated in the median line by the aperture of the vagina.

The Compressor Urethrae (Transversus perinei profundus) is the analogue of the Compressor urethrae in the male. It arises from the ischio-pubic ramus, and, passing inward, its anterior fibres blend with the muscle of the opposite side, in front of the urethra; its middle fibres, the most numerous, are inserted into the side of the vagina, and the posterior fibres join the central point of the perineum.

The distribution of the internal pudic artery is the same as in the male (see page 625), and the pudic nerve has also a similar arrangement, the dorsal nerve being, however, very small and supplying the clitoris.

The corpus spongiosum is divided into two lateral halves, which are represented by the bulbi vestibuli and partes intermediales (see page 1165).

The perineal body fills up the interval between the lower part of the vagina and the rectum. Its base is covered by the skin lying between the anus and vagina on what is called the "perineum." Its anterior surface lies behind the posterior vaginal wall, and its posterior surface lies in front of the anterior rectal wall and the anus. It measures about an inch and a quarter from before backward, and laterally extends from one tuberosity of the ischium to the other. In it are attached the muscles belonging to the external organs of generation. Through its
centre runs the transverse perineal septum, which is of great strength in women, and forms on either side, behind the posterior commissure, a hard, ill-defined body, consisting of connective tissue, with much yellow elastic tissue and interlacing bundles of involuntary muscular fibres, in which the voluntary muscles of the perineum are inserted.

**PELVIC FASCIA.**

The Pelvic fascia (Fig. 772) is a thin membrane which lines the whole of the cavity of the pelvis and is continuous with the transversalis and iliace fasciae. It is attached to the brim of the pelvis, for a short distance, at the side of the cavity, and to the inner surface of the bone round the attachment of the Obturator internus. At the posterior border of this muscle it is continued backward as a very thin membrane in front of the Pyriformis muscle and sacral nerves to the front of the sacrum. In front it follows the attachment of the Obturator internus to the bone, arches beneath the obturator vessels, completing the orifice of the obturator canal, and at the front of the pelvis is attached to the lower part of the symphysis pubis. At the level of a line extending from the lower part of the symphysis pubis to the

![Fig. 772.—Side view of the pelvic viscera of the male subject, showing the pelvic and perineal fasciae.](image_url)

spine of the ischium is a thickened whitish band; this marks the attachment of the Levator ani muscle to the pelvic fascia, and corresponds to its point of division into two layers, the obturator and recto-vesical.

The obturator fascia descends and covers the Obturator internus muscle. It is a direct continuation of the pelvic fascia below the white line above mentioned, and is attached to the pubic arch and to the margin of the great sacro-sciatic ligament. From its attachment to the rami of the os pubis and ischium a process is given off which is continuous with a similar process from the opposite side, so as to close the front part of the outlet of the pelvis, forming the superior layer of the triangular ligament. This fascia forms a canal for the pudic vessels and nerve in their passage forward to the perineum, and gives off a thin membrane
which covers the perineal aspect of the Levator ani muscle, called the ischio-rectal (anal) fascia.

The recto-vesical fascia (visceral layer of the pelvic fascia) descends into the pelvis upon the upper surface of the Levator ani muscle, and invests the prostate, bladder, and rectum. From the inner surface of the symphysis pubis a short rounded band is continued to the anterior surface of the prostate and neck of the bladder, forming the pubo-prostatic or anterior true ligaments of the bladder. At the side this fascia is connected to the side of the prostate, enclosing this gland and the vesico-prostatic plexus of veins, and is continued upward on the side of the bladder, forming the lateral true ligaments of the organ. Another prolongation invests the vesiculae seminales, and passes across between the bladder and rectum, being continuous with the same fascia of the opposite side. Another thin prolongation is reflected round the surface of the lower end of the rectum. The Levator ani muscle arises from the point of division of the pelvic fascia, the visceral layer of the fascia descending upon and being intimately adherent to the upper surface of the muscle, while the under surface of the muscle is covered by a thin layer derived from the obturator fascia, called the ischio-rectal or anal fascia. In the female the vagina perforates the recto-vesical fascia, and receives a prolongation from it.

The books in the annexed list will be sent by mail, post-paid, to any Post-Office in the United States, on receipt of the printed prices. No risks of the mail, however, are assumed either on money or books. Intending purchasers will therefore in most cases find it more convenient to deal with the nearest bookseller.

STANDARD MEDICAL PERIODICALS.

Progressive Medicine.
A Quarterly Digest of New Methods, Discoveries and Improvements in the Medical and Surgical Sciences by Eminent Authorities. Edited by DR. HOBART AMORY HARE. In four abundantly illustrated, cloth bound, octavo volumes of 400-500 pages each, issued quarterly, commencing March 1, 1899. Per annum (4 volumes), $10.00, delivered.

The Medical News.
WEEKLY, $4.00 PER ANNUM.
Each number contains 32 quarto pages, abundantly illustrated. A crisp, fresh weekly professional newspaper.

The American Journal of the Medical Sciences.
MONTHLY, $4.00 PER ANNUM.
Each issue contains 128 octavo pages, fully illustrated. The most advanced and enterprising American exponent of scientific medicine.

The Medical News Visiting List for 1900.
Four styles, Weekly (dated for 30 patients); Monthly (undated, for 120 patients per month); Perpetual (undated, for 30 patients weekly per year); and Perpetual (undated, for 60 patients weekly per year). Each style in one wallet-shaped book, leather bound, with pocket, pencil and rubber. Price, each, $1.25. Thumb-letter index, 25 cents extra.

The Medical News Pocket Formulary for 1900.
Containing 1700 prescriptions representing the latest and most approved methods of administering remedial agents. Strongly bound in leather, with pocket and pencil. Price, $1.50, net.

ALLEN (HARRISON). A SYSTEM OF HUMAN ANATOMY; WITH AN INTRODUCTORY SECTION ON HISTOLOGY, by E. O. SHAKESPEARE, M.D. Comprising 813 double-columned quarto pages, with 380 engravings on stone on 109 full-page plates, and 241 woodcuts. One volume, cloth, $23. Sold by subscription only.

A TREATISE ON SURGERY BY AMERICAN AUTHORS. FOR STUDENTS AND PRACTITIONERS OF SURGERY AND MEDICINE. Edited by ROSEWELL PARK, M.D. New condensed edition. In one large octavo volume of 1261 pages, with 625 engravings and 38 plates. Just ready. Cloth, net, $6.00; leather, net, $7.00. This work is published also in a large edition, comprising two octavo volumes. Vol. I., General Surgery, 790 pages, with 326 engravings and 21 full-page plates in colors and monochrome. Vol. II., Special Surgery, 796 pages, with 451 engravings and 17 full-page plates in colors and monochrome. Price per volume, cloth. $4.50; leather, $5.50, net.

AMERICAN SYSTEM OF PRACTICAL MEDICINE. A SYSTEM OF PRACTICAL MEDICINE. In Contributions by Eminent American Authors. Edited by ALFRED L. LOOMIS, M.D., LL.D., and W. GILMAN THOMPSON, M.D. In four very handsome octavo volumes of about 900 pages each, fully illustrated. Complete work now ready. Per volume, cloth, $5; leather, $6; half Morocco, $7. For sale by subscription only. Prospectus free on application.

AMERICAN SYSTEM OF DENTISTRY. IN TREATISES BY VARIOUS AUTHORS. Edited by WILBUR F. LITCH, M.D., D.D.S. In four very handsome super-royal octavo volumes, containing about 4000 pages, with about 2200 illustrations and many full-page plates. Volume IV., preparing. Per volume, cloth, $6; leather, $7; half Morocco, $8. For sale by subscription only. Prospectus free on application to the Publishers.

AMERICAN TEXT-BOOKS OF DENTISTRY. IN CONTRIBUTIONS BY EMINENT AMERICAN AUTHORITIES. In two octavo volumes of 600–800 pages each, richly illustrated:

PROSTHETIC DENTISTRY. Edited by CHARLES J. ESSIG, M.D., D.D.S., Professor of Mechanical Dentistry and Metallurgy, Department of Dentistry, University of Pennsylvania, Philadelphia. 760 pages, 983 engravings. Cloth, $6; leather, $7, net.

OPERATIVE DENTISTRY. Edited by EDWARD C. KIRK, D.D.S., Professor of Clinical Dentistry, Department of Dentistry, University of Pennsylvania. 700 pages, 751 engravings. Cloth, $5.50; leather, $6.50, net.

AMERICAN SYSTEMS OF GYNECOLOGY AND OBSTETRICS. In treatises by the most eminent American specialists. Gynecology edited by MATTHEW D. MAYN, A.M., M.D., and Obstetrics edited by BARTON C. HIRST, M.D. In five large octavo volumes comprising 3612 pages, with 1092 engravings, and 8 colored plates. Per volume, cloth, $5; leather, $6; half Russia, $7. For sale by subscription only. Prospectus free.

ASHHURST (JOHN, JR.). THE PRINCIPLES AND PRACTICE OF SURGERY. For the use of Students and Practitioners. Sixth and revised edition. In one large and handsome 8vo. volume of 1161 pages, with 656 engravings. Cloth, $6; leather, $7.

A SYSTEM OF PRACTICAL MEDICINE BY AMERICAN AUTHORS. Edited by WILLIAM PEPPER, M.D., LL.D. In five large octavo volumes, containing 5573 pages and 198 illustrations. Price per volume, cloth, $5; leather, $6; half Russia, $7. Sold by subscription only. Prospectus free on application to the Publishers.

A PRACTICE OF OBSTETRICS BY AMERICAN AUTHORS. See Jewett, page 9.

ATTFIELD (JOHN). CHEMISTRY; GENERAL, MEDICAL AND PHARMACEUTICAL. New (16th) edition, specially revised by the Author for America. In one handsome 12mo. volume of 784 pages, with 88 illustrations. Cloth, $2.50, net.

Philadelphia, 106 708 and 710 Sansom St.—New York, 111 Fifth Avenue.
LEA BROTHERS & CO.'S PUBLICATIONS.

BACON (GORHAM). ON-THE EAR. One 12mo. volume, 398 pages, with 100 engravings and one colored plate. Cloth, $2, net.

BARNES (ROBERT AND FANCOURT). A SYSTEM OF OBSTETRIC MEDICINE AND SURGERY, THEORETICAL AND CLINICAL. The Section on Embryology by PROF. MILNES MARSHALL. In one large octavo volume of 872 pages, with 231 illustrations. Cloth, $5; leather, $6.

BARTHOLOW (ROBERTS). CHOLERA; ITS CAUSATION, PREVENTION AND TREATMENT. In one 12mo. volume of 127 pages, with 9 illustrations. Cloth, $1.25.

BILLINGS (JOHN S.). THE NATIONAL MEDICAL DICTIONARY. Including in one alphabet English, French, German, Italian and Latin Technical Terms used in Medicine and the Collateral Sciences. In two very handsome imperial octavo volumes, containing 1574 pages and two colored plates. Per volume, cloth, $6; leather, $7; half Morocco, $8.50. For sale by subscription only. Specimen pages on application.

BLACK (D. CAMPBELL). THE URINE IN HEALTH AND DISEASE, AND URINARY ANALYSIS, PHYSIOLOGICALLY AND PATHOLOGICALLY CONSIDERED. In one 12mo. volume of 256 pages, with 73 engravings Cloth, $2.75.

—— PRINCIPLES OF TREATMENT. In one octavo volume of 625 pages. Just Ready. Cloth, $3.75, net.

BURCHARD (HENRY H.). DENTAL PATHOLOGY AND THERAPEUTICS, INCLUDING PHARMACOLOGY. Handsome octavo, 575 pages, with 400 illustrations. Cloth, $5; leather, $8, net.

CHARLES (T. CRANSTOUN). THE ELEMENTS OF PHYSIOLOGICAL AND PATHOLOGICAL CHEMISTRY. In one handsome octavo volume of 451 pages, with 38 engravings and 1 colored plate. Cloth, $3.50.

CHEYNE (W. WATSON). THE TREATMENT OF WOUNDS, ULCERS AND ABSCESSES. In one 12mo. volume of 207 pages. Cloth, $1.25.

CLELAND (JOHN). A DIRECTORY FOR THE DISSECTION OF THE HUMAN BODY. In one 12mo. volume of 178 pages. Cloth, $1.25.

CLOWES (FRANK). AN ELEMENTARY TREATISE ON PRACTICAL CHEMISTRY AND QUALITATIVE INORGANIC ANALYSIS. From the fourth English edition. In one handsome 12mo. volume of 387 pages, with 55 engravings. Cloth, $2.50.

COATES (W. E., Jr.). A POCKET TEXT-BOOK OF BACTERIOLOGY AND HYGIENE. 12mo., of about 350 pages with many illustrations. Shortly.

COATS (JOSEPH). A TREATISE ON PATHOLOGY. In one volume of 829 pages, with 339 engravings. Cloth, $5.50; leather, $6.50.

COLLINS (H. D.) AND ROCKWELL (W. H., Jr.). A POCKET TEXT-BOOK OF PHYSIOLOGY. 12mo., of 316 pages, with 133 Illustrations. Just Ready. Cloth; $1.50, net; flexible. red leather, $2.00, net.

CORNIL (V.). SYPHILIS: ITS MORBID ANATOMY, DIAGNOSIS AND TREATMENT. Translated, with Notes and Additions, by J. HENRY C. SIMES, M.D., and J. WILLIAM WHITE, M.D. In one 8vo. volume of 461 pages, with 84 illustrations. Cloth, $3.75.

Philadelphia, 706, 708 and 710 Sansom St.—New York, 111 Fifth Avenue.

CULBRETH (DAVID M.R.). MATERIA MEDICA AND PHARMACOLOGY. In one handsome octavo volume of 812 pages, with 445 engravings. Cloth, $4.75.

— DOCTRINES OF THE CIRCULATION OF THE BLOOD. In one handsome 12mo. volume of 293 pages. Cloth, $2.

DAVIS (EDWARD P.). A TREATISE ON OBSTETRICS. For Students and Practitioners. In one very handsome octavo volume of 546 pages, with 217 engravings, and 30 full-page plates in colors and monochrome. Cloth, $5; leather, $6.

DE LA BECHE'S GEOLOGICAL OBSERVER. In one large octavo volume of 700 pages, with 300 engravings. Cloth, $4.

DENNIS (FREDERIC S.) AND BILLINGS (JOHN S.). A SYSTEM OF SURGERY. In Contributions by American Authors. In four very handsome octavo volumes, containing 3652 pages, with 1655 engravings, and 45 full-page plates in colors and monochrome. Per volume, cloth, $6; leather, $7; half Morocco, gilt back and top, $8.50. For sale by subscription only. Full prospectus free.

DERCUM (FRANCIS X.), Editor. A TEXT-BOOK ON NERVOUS DISEASES. By American Authors. In one handsome octavo volume of 1064 pages, with 341 engravings and 7 colored plates. Cloth, $6; leather, $7, net.

DUDLEY (E. C.). A TREATISE ON THE PRINCIPLES AND PRACTICE OF GYNECOLOGY. For Students and Practitioners. New (2d) edition. In one very handsome octavo volume of 717 pages, with 453 engravings, of which 47 are colored, and 8 full page plates in colors and monochrome. Just Ready. Cloth, $5.00, net; leather, $6.00, net; half morocco, $6.50, net.

Philadelphia, 706, 708 and 710 Sansom St.—New York, 111 Fifth Avenue.
DUNGLISON (ROBLEY). A DICTIONARY OF MEDICAL SCIENCE. Containing a full Explanation of the Various Subjects and Terms of Anatomy, Physiology, Medical Chemistry, Pharmacy, Pharmacology, Therapeutics, Medicine, Hygiene, Dietetics, Pathology, Surgery, Ophthalmology, Otology, Laryngology, Dermatology, Gynecology, Obstetrics, Pediatrics, Medical Jurisprudence, Dentistry, etc., etc. By ROBLEY DUNGLISON, M.D., LL.D., late Professor of Institutes of Medicine in the Jefferson Medical College of Philadelphia. Edited by RICHARD J. DUNGLISON, A.M., M.D. Twenty-second edition, thoroughly revised and greatly enlarged and improved, with the Pronunciation, Accentuation and Derivation of the Terms. With Appendix. Imperial octavo of about 1400 pages. Shortly.

EDES (ROBERT T.). TEXT-BOOK OF THERAPEUTICS AND MATERIA MEDICA. In one 8vo. volume of 544 pages. Cloth, $3.50; leather, $4.50.

EGERT (SENECA). HYGIENE AND SANITATION. In one 12mo. volume of 359 pages, with 83 illustrations. Cloth, $2.25, net.

EMMET (THOMAS ADDIS). THE PRINCIPLES AND PRACTICE OF GYNAECOLOGY. For the use of Students and Practitioners. Third edition, enlarged and revised. 8vo. of 880 pages, with 150 original engravings. Cloth, $5; leather, $6.

FARQUHARSON (ROBERT). A GUIDE TO THERAPEUTICS. Fourth American from fourth English edition, revised by FRANK WOODBURY, M.D. In one 12mo. volume of 581 pages. Cloth, $2.50.

FLINT (AUSTIN). A TREATISE ON THE PRINCIPLES AND PRACTICE OF MEDICINE. New (7th) edition, thoroughly revised by FREDERICK P. HENRY, M.D. In one large 8vo. volume of 1143 pages, with engravings. Cloth, $6; leather, $6.

— A MANUAL OF AUSCULTATION AND PERCUSSION; of the Physical Diagnosis of Diseases of the Lungs and Heart, and of Thoracic Aneurism. Fifth edition, revised by JAMES C. WILSON, M.D. In one handsome 12mo. volume of 274 pages, with 12 engravings.

— MEDICAL ESSAYS. In one 12mo. volume of 210 pages. Cloth, $1.38.

— ON PITHESIS; ITS MORBID ANATOMY, ETIOLOGY, ETC. A Series of Clinical Lectures. In one 8vo. volume of 442 pages. Cloth, $3.50.

Philadelphia, 706, 708 and 710 Sansom St.—New York, 111 Fifth Avenue.
FOLSOM (C. F.). AN ABSTRACT OF STATUTES OF U. S. ON CUSTODY OF THE INSANE. In one 8vo. volume of 108 pages. Cloth, $1.50. With Clouston on Mental Diseases (see page 4), at $5.00, net, for the two works.

FORMULARY, POCKET. See page 1.

FOSTER (MICHAEL). A TEXT-BOOK OF PHYSIOLOGY. New (6th) and revised American from the sixth English edition. In one large octavo volume of 923 pages, with 257 illustrations. Cloth, $4.50; leather, $5.50.

FRANKLAND (E.) AND JAPP (F. R.). INORGANIC CHEMISTRY. In one handsome octavo volume of 677 pages, with 51 engravings and 2 plates. Cloth, $3.75; leather, $4.75.

FULLER (EUGENE). DISORDERS OF THE SEXUAL ORGANS IN THE MALE. In one very handsome octavo volume of 238 pages, with 25 engravings and 8 full-page plates. Cloth, $2.

GALLAUDET (BERN B.). A POCKET TEXT-BOOK ON SURGERY. 12mo. of about 400 pages, with many illustrations. Shortly.

GERRISH (FREDERICK H.). A TEXT-BOOK OF ANATOMY. By American Authors. Edited by Frederick H. Gerrish, M.D. In one imp. octavo volume of 915 pages, with 950 illustrations in black and colors. Cloth, $6.50; flexible water-proof, $7; sheep, $7.50, net.

GIBBES (HENEAGE). PRACTICAL PATHOLOGY AND MORBID HISTOLOGY. Octavo of 314 pages, with 60 illustrations, mostly photographic. Cloth, $2.75.

GRAY (HENRY). ANATOMY, DESCRIPTIVE AND SURGICAL. New American edition thoroughly revised. In one imperial octavo volume of 1239 pages, with 772 large and elaborate engravings. Price with illustrations in colors, cloth, $7; leather, $8. Price, with illustrations in black, cloth, $6; leather, $7.

GREENE (WILLIAM H.). A MANUAL OF MEDICAL CHEMISTRY. For the Use of Students. Based upon Bowman's Medical Chemistry. In one 12mo. volume of 310 pages, with 74 illustrations. Cloth, $1.75.

Philadelphia, 706, 708 and 710 Sansom St.—New York, 111 Fifth Avenue.
HALL (WINFIELD S.). TEXT-BOOK OF PHYSIOLOGY. Octavo, 672 pages, with 543 engravings and 6 colored plates. Just Ready. Cloth, $4.00, net; leather, $5.00, net.

HARE (HOBABT AMORY). A TEXT-BOOK OF PRACTICAL THERAPEUTICS, with Special Reference to the Application of Remedial Measures to Disease and their Employment upon a Rational Basis. With articles on various subjects by well-known specialists. New (8th) and revised edition. In one octavo volume of 796 pages, with 57 engravings and 3 colored plates. Just Ready. Cloth, $4.00, net; leather, $5.00, net.
